Freeze-drying operations are used because of limited stability of certain drugs in solution. Most therapeutic proteins are unstable in solution and can only be commercial products if they are freeze-dried. Freeze-dried formulations usually contain bulking agents (e.g., mannitol) that provide an esthetic dry solid matrix and can help in stabilizing the drug in the solid state. Other excipients are added to the freeze-dried formulation for various reasons, primarily to aid in product chemical and/or physical stabilization (e.g., buffers, antioxidants, cryoprotectants). Freeze-dried vials are usually stable for at least 2 years at ambient conditions, except for some protein products that might need to be refrigerated and have a shorter shelf life. Once the freeze-dried product is reconstituted, normal shelf-life storage conditions are 24 h at room temperature and up to 1 week under refrigeration. Excellent freeze-drying science and technology reviews are available (16, 17).

Powder-filled SVIs

Many SVI antibiotics, particularly the injectable cephalosporins, as well as other molecules are manufactured by sterile crystallization of the active ingredient and aseptically filling the sterile powder into the final container. The drug is dissolved in an appropriate solvent, then filtered through a 0.2- μ m membrane filter. Several techniques can be used for sterile crystallization, including adding sterile seed crystals and adjusting the pH level or adding a sterile antisolvent in which the drug is insoluble. The resultant slurry is collected on a filter system (e.g., the Buchner funnel) and dried, then the dried crystals are milled and blended. Obviously, for this approach to work, the drug must be able to be crystallized. Several variables are critical in controlling the purity and quality of the final crystals, including temperature, rate of addition of solvent, adjustment of pH level, mixing rate and time, and the quality of the seed crystals. Sterile crystallization followed by powder-filling is much more economical than freeze-drying. However, sterile powder-filling offers greater challenges with respect to process variability, microbial and particulate contamination, and operator sensitivity.

Suspensions (18)

With sterile suspensions, the active drug ingredient is suspended in a liquid carrier before administration. Commercial suspensions are either ready to use or dry powders reconstituted as suspensions. Drugs

are formulated as suspension dosage forms for one of two reasons:

- poor solubility in aqueous solution but the product does not need to be administered iv, and
- the need for a long-acting depot injection.

Suspension products (Table 4) are prepared by combining sterile vehicle and sterile drug powder aseptically or by combining two sterile solutions, with the drug solution precipitating in the diluent solution.

Major concerns with the suspension dosage form are:

1. Resuspendability of the drug in the vehicle to permit homogeneous filling of the product into the container and to provide homogeneous dosing when withdrawing from the container;
2. Caking or settling of the drug, resulting in a physically unstable product; and
3. Syringeability (the ability to withdraw a homogeneous dose from the vial into a syringe) and injectability (the ability to eject the product through the needle into the patient).

Formulation ingredients include the suspending agent, a wetting agent (if the suspending agent does not also serve this purpose), a buffer, and an antimicrobial preservative for multiple-dose products.

Emulsions (19)

Emulsions are mixtures of oil- and water-based vehicles with an appropriate surface-active agent to facilitate and maintain the miscibility of the oil-in-water phase. Diprivan® (propofol, a local anesthetic agent) is a primary example of an SVI emulsion. The formulation contains soybean oil, glycerol, and egg lecithin.

BASIC CHARACTERISTICS OF SVIs

SVIs must be sterile and free from pyrogens and foreign particulate matter. These three major characteristics distinguish sterile dosage forms from any other pharmaceutical product.

Sterility (20)

Sterility is a state of absolute freedom from microbial contamination. Interestingly, the word *sterile* on the label of a sterile product has had a historic meaning that a sample of the product lot passed the compendial test for sterility (21). Today, to claim that a product is sterile involves much more than passing a sterility test. Achievement of sterility involves the combination and coordination of a wide range of activities and processes such as:

Cleaning and sanitization of all facilities and equipment

Cleaning and sterilization of equipment, packaging, and all other items to be in contact with the sterile product

Installation and certification of laminar air flow areas where sterile air is provided via high-efficiency particulate air (HEPA) filters

Environmental monitoring of the facility, equipment, water, and personnel for strict microbiological and particulate control

Appropriate gowning and training of personnel in aseptic techniques

Table 4 Small-volume parenteral suspensions

Product	Manufacturer	Suspending agent
Aristocort	Lederle	Propylene glycol 4000
Bicillin C-R	Wyeth	Lecithin, carboxymethylcellulose
Decadron-LA	Merck	Carboxymethylcellulose
Depo-medrol	Upjohn	PEG 3350 (polyethylene glycol)
Duracillin	Lilly	Procaine salt
Hydeltra-TBA	Merck	Tebutate salt
Lente insulins	Lilly, Novo	Polymorphic
NPH insulins	Lilly, Novo	Protamine
PZI insulins	Lilly, Novo	Protamine, zinc
Prolixin decanoate	Princeton	Decanoate salt

Validation of sterilization processes

Validation of the filter system

Integrity testing of the filter system before and after filtration

Integrity testing of the container-closure system to maintain sterility of the product

Conductance of the sterility test initially for all lots and at the end of the shelf-life expiration dating period for the product lot under stability testing

The end-product sterility test suffers from at least three serious limitations that minimize its dependability as a sole indicator of the sterility of a lot of product.

1. Concern that the small sample (usually 20 containers per lot) truly represents the entire lot. Probability statistics reveal that with such a small sample size, the extent of contamination must be significant (on the order of at least 1% of the lot) for the sample to fail the sterility test.
2. Concern that the culture test media used for sterility testing can support the growth of low to high levels of any microbial life possibly contaminating the product.
3. Concern that no accidental contamination was introduced during the performance of the sterility test. There is a finite probability that personnel, testing environment, and/or testing materials may introduce contamination, resulting in a false-positive sterility test result. This concern has been alleviated to a great degree by the advent and successful application of barrier isolator technology systems. Such systems remove direct human contact with the sterile product samples and provide a testing environment that is validated as truly sterile.

Freedom from Pyrogens

Pyrogens are metabolic byproducts of microbial growth. Injected in sufficient amounts in humans (in fact, in any mammal), pyrogens can react with the hypothalamus of the brain to raise the body temperature. In addition, they can cause a number of other adverse physiological effects, including death. The serious problems with sepsis are a result of high levels of endotoxins, endotoxins being a major type of pyrogen. Pyrogens are very small, water-soluble, heat-resistant lipopolysaccharides that cannot be destroyed by typical steam-sterilization cycles or removed by 0.2- μ m membrane

filters. Prevention rather than elimination is the key for pyrogen removal. The primary source of pyrogenic contamination in parenteral products is water. Fortunately, pyrogens are destroyed by distillation. Water used to clean containers and closures can also be a source of pyrogens. However, glass is sterilized by dry heat at temperatures hot enough (usually $>250^{\circ}\text{C}$ to destroy pyrogens). Rubber closures are steam-sterilized, which does not destroy pyrogens. Closures are depyrogenated by the cleaning and rinsing process using pyrogen-free water. Chemical raw materials used in parenteral formulations must be crystallized using pyrogen-free water or other solvents. Some raw materials, e.g., sucrose, mannitol, amino acids, etc. must now be tested by incoming quality control for the presence of endotoxins. If the parenteral product is contaminated with pyrogens, there is no practical way to remove or destroy them. Ultrafiltration (nanometer; nominal molecular-weight filters) will depyrogenate and is used in bioprocessing for separating the smallest unit of lipopolysaccharide from therapeutic proteins. However, ultrafiltration is not a practical pyrogen-removal process for commercial processing of parenteral products.

Pyrogenic contamination is detected using two tests. In the older method, rabbits are injected with product samples, and rectal temperature is measured. Compensatory limits are established with respect to how much temperature increase is permitted before the product is judged to be free or contaminated with pyrogens. The newer method involves a relatively simple in vitro technique called the Limulus Amebocyte Lysate (LAL) test. It is based on the high sensitivity of amebocytes of the horseshoe crab (*Limulus*) to the lipopolysaccharide component of endotoxins originating from Gram-negative bacteria. The LAL test is now the USP method of choice with endotoxin limits established for most SVIs (22).

Freedom from Particulate Matter

Particulate matter is viewed as unacceptable contamination in parenteral solutions. It is recognized that subvisible particulate matter will exist in certain amounts, but the USP now has limits for acceptable levels of particulate matter for SVIs (no more than 6000 particles per container $\geq 0.5\ \mu\text{m}$; no more than 600 particles per container $\geq 25\ \mu\text{m}$). The USP is the only compendium in the world that contains limits for subvisible particulates in SVIs. All worldwide compendia have subvisible particle limits (particles per milliliter) for large-volume injections. SVI solutions with

visible particulate matter should not be used. Particulate matter creates problems in product quality and clinical safety. The primary sources of particulate matter are the container-closure systems and personnel.

Stability

Drugs in SVIs are generally unstable. Many drugs are so unstable that they cannot be marketed as ready-to-use solutions. Drugs with sufficient solution stability will still require certain formulation, packaging, and storage conditions to maintain stability during shelf-life storage and use. The primary pathways of drug degradation involve oxidation (reaction with molecular oxygen catalyzed by various factors including high temperature, high pH level, heavy metals, light, and peroxide contaminants) and hydrolysis (reaction with water catalyzed by high temperature and extremes in pH). For protein pharmaceuticals, aggregation of the protein, resulting in a loss of potency, can be a major degradation pathway. Drugs can also react with packaging and formulation components, resulting in physical and chemical degradation.

Oxidation involves the reaction of free radicals with molecular oxygen so the combination of functional groups that can easily form free radicals, e.g., phenolic or sulfhydryl groups, catalysts (see above), and molecular oxygen, will cause a propagation of the self-oxidation process. Many SVI products are packaged in light-protective packaging, require storage at controlled room or lower (refrigeration) temperatures, are formulated at low pH, contain antioxidants and/or metal chelating agents, and are processed in “oxygen-free” conditions where water is saturated with an inert gas, and, before to sealing the container, the product is overlaid with an inert gas to remove oxygen from the headspace of the container.

Many drugs in liquid SVIs will react with water and form hydrolytic degradation products. Hydrolysis and decomposition occur as solution pH may change and are catalyzed by resulting hydrogen and/or hydroxyl ions. Buffers play an important role in certain injectable products to achieve tight control of solution pH. Hydrolysis of solid-state injectables can occur with moisture from the headspace in the container, moisture remaining in the solid product, and/or moisture originating from or through the rubber closure. Control of residual moisture during and after processing and the use of effective container-closure systems to minimize moisture ingress are very important to protect dried powders from hydrolytic degradation.

Isotonicity

SVIs should be isotonic with blood, tears, spinal fluid, and other biological fluids into which the product is injected or instilled. This means that the injected or instilled solution contains the same “number” of solute “particles” in solution as is contained in the biological cell. Isotonicity means that the “tone” of the cell will not be disturbed, either by the ingress of water from the injected solution (if the solution is hypotonic) or egress of water from the cell (if the solution is hypertonic). Solution tonicity can be ascertained by measurement of a colligative property such as osmotic pressure or freezing-point depression. Biological cells are semipermeable membranes, meaning that they allow the passage of water (and some solutes such as boric acid) but do not allow passage of most solutes. Thus, for example, if a hypotonic solution is injected or instilled, there are fewer solute “particles” in the solution than there are in the cell, forcing water from the injected solution to pass through the cell membrane in an attempt to equalize pressure on both sides of the cell membrane. Increasing the water level of the cell may lead to the cell bursting, which, for red blood cells, is a phenomenon called hemolysis. Hypertonic solutions administered cause the opposite effect, whereby water from the cells permeates the membrane to equalize pressure, and the cells shrink (crenation). In either case, cellular damage can occur causing pain and tissue irritation or damage. Blood, muscle, and subcutaneous cells can withstand a fairly wide range of osmotic pressures from injected solutions (e.g., 250–350 mOsm/kg), whereas tear and spinal fluid cells are much more sensitive to slight differences in the osmotic pressure of injected or instilled solutions. In practice, wide osmolality ranges of SVIs can be tolerated when injected except for injections in cerebrospinal fluid (intrathecal, intraspinal, intracisternal injections). However, it is also true that for all injections, achieving isotonicity should be a goal of the product formulation scientist.

FORMULATION INGREDIENTS

SVIs are simple formulations compared with other pharmaceutical dosage forms. Solution SVIs contain water, the active ingredient, and a minimal number of inactive added ingredients. Solid SVIs contain the active ingredient and usually one or two added ingredients. Formulation scientists have severe restrictions in number and choice of added substances because of safety considerations.

Solvent

The most widely used solvent for SVIs is water for injection (WFI), USP. As a solvent, WFI is used in preparing the bulk solution (compounding) and as a final rinse for equipment and packaging preparation. WFI is prepared by distillation or reverse osmosis, although only distillation is permitted for sterile water for injection, USP. Sterile water for injection is used as a vehicle for reconstitution of sterile solid products before administration and is terminally sterilized by autoclaving. Bacteriostatic water for injection, USP, is commercially available as a reconstitution vehicle for solid products intended for multiple-dose use. Benzyl alcohol is a common antimicrobial preservative used in bacteriostatic water for injection.

Sesame oil, cottonseed oil, and other vegetable oils are used as vehicles for water-insoluble drugs such as corticosteroids and oil-soluble vitamins. Oily solutions can be administered only by intramuscular injection.

Solubilizers

Solubilizers are used to enhance and maintain the aqueous solubility of poorly water-soluble drugs (23–27). Examples of solubilizing agents used in sterile products include:

1. *Liquid cosolvents*: glycerin, polyethylene glycol (300, 400, 3350), propylene alcohol, and ethanol, Cremophor EL, sorbitol
2. *Surface active agents*: polysorbate 80 (polyoxyethylene sorbitan monooleate), polysorbate 20, Pluronic 68, lecithin
3. *Complexing agents*: β -Cyclodextrins, Captisol[®], polyvinylpyrrolidone, carboxymethylcellulose sodium

Liquid solubilizers act by reducing the dielectric constant properties of the solvent system, thereby reducing the electrical conductance capabilities of the solvent and increasing the solubility of hydrophobic or nonpolar drugs. Lanoxin[®], Valium[®], and Nembutal[®] are examples of commercially available sterile solutions containing cosolvent solubilizers. A popular combination consists of 40% propylene glycol and 10% ethanol in water.

Surface active agents increase the dispersability and water solubility of poorly soluble drugs owing to their unique chemical properties of possessing both hydrophilic and hydrophobic functional groups in the same molecule (the same is true of β -Cyclodextrins, addressed below). The hydrophobic groups adsorb to surface molecules of the drug, whereas the hydrophilic groups interact with the

water-solvent molecules. Therefore, the drug molecules locate within the hydrophobic core of the surface active agent (sometimes called a micelle) while the polar molecules of the surface active agent are oriented with water, and the drug is solubilized within the surface active agent dissolved in water.

Solid solubilizers such as the β -Cyclodextrins act by forming soluble inclusion complexes in aqueous solution. These molecules, as with surface active agents, are amphiphilic, meaning that they contain hydrophobic interior functional groups and hydrophilic hydroxy exterior functional groups that enable insoluble drugs to remain in the interior core and be solubilized in water. Brewster, et al. (28) reviewed the application of cyclodextrins in parenteral formulations, particularly for the solubilization and stabilization of proteins and peptides. A relatively new cyclodextrin, Captisol[®], has gained prominence as a safe and effective solubilizer and stabilizer (29). It is an anionic β -Cyclodextrin with a sulfobutyl ether substituent.

Antimicrobial Preservative Agents

Antimicrobial preservatives serve to maintain the sterility of the product during its shelf life and use. They are required in preparations intended for multiple dosing from the same container because of the finite probability of accidental contamination during repeated use. They also are included, although this is quite controversial, in some single-dose products that are aseptically manufactured to provide additional assurance of product sterility. The combination of antimicrobial preservative agents and adjunctive heat treatment (usually temperatures below 110°C) also is used to increase assurance of sterility for products that cannot be terminally sterilized. Very few antimicrobial preservative agents are acceptable (Table 5), with this list decreasing as agents such as thimerosal (and other mercury-containing preservatives) and chlorobutanol are no longer being used. Most substances with antimicrobial activity are irritating and toxic at relatively low concentrations and usually have stability limitations (hydrolytic or oxidative degradation). They can be incompatible with the drug and formulation ingredients and can interact adversely with packaging components. Most commonly used parenteral antimicrobial preservatives are alcoholic or phenolic chemicals. These are highly toxic even at low concentrations and easily oxidizable, and their volatility can cause problems with rubber closure permeation. Formulation scientists must also be aware of significant differences comparing USP and EP requirements for preservative efficacy. Basically, the USP

Table 5 Antimicrobial preservative agents in Small-volume parenterals

Agent	Concentration range (%)	Products
Phenol	0.065–0.5	Humulin N, Zantac, Tensilon, Tagamet, Phenergan, Imferon
<i>m</i> -Cresol	0.16–0.3	Humulin N, Humulin R, Humatrope, Demerol
Methylparaben	0.05–0.18	Decadron, Elavil, Prostigmin
Propylparaben	0.011–0.035	Garamycin, Prolixin, Bicillin
Chlorobutanol	0.5–0.55	Epitrate, Bentyt, Dopram
Benzyl alcohol	0.75–2.0	Valium, Protopin, Geopen, Compazine, Pronestyl, Cleocin
Benzalkonium chloride	0.01–0.025	Most ophthalmic products
Thimerosal	0.0075–0.01	Neosporin, Rhogam, Wydase

requires a bacteriostatic preservative system, whereas the EP requires a bacteriocidal preservative system. For example, whereas the USP requires a 1-log reduction 7 days after a bacterial challenge population is added to the product containing the antimicrobial preservative, the EP Criteria A requirement is a 3-log reduction in bacterial population after 1 day.

Buffers

Buffers are used to maintain the pH level of a solution in the range that provides either maximum stability of the drug against hydrolytic degradation or maximum or optimal solubility of the drug in solution. The most common buffer systems used in SVIs are listed in Table 6. Buffers are composed of simple weak acids and their corresponding salt forms. The appropriate choice of buffer depends on the pH range in which the drug in question is most stable (or most soluble) that matches the pK_a (dissociation constant) of the buffer species. For example, if a pH of 4.5 is most desirable, the correct choice of buffer would be an acetate buffer because the pK_a of acetic acid is 4.76. At pH 4.76, acetic acid exists 50% as the acid (unionized form) and 50% as the salt (ionized form). Sufficient acid and salt species exist at this pH level to compensate for any potential drifts in solution pH and maintain the desired pH level. The concentration of buffer

depends on strength of buffer capacity required to maintain the pH level within the desired range. Obviously, the higher the concentration, the greater the buffer capacity. However, high buffer concentrations can lead to other problems such as general acid/base catalysis of drug hydrolytic reactions.

Antioxidants (30)

Antioxidants function by reacting preferentially with molecular oxygen and minimizing or terminating the free radical auto-oxidation reaction. Many drugs are sensitive to the presence of oxygen and will degrade very rapidly in the absence of protection. In addition to the use of antioxidants, other precautions must be taken. These include protection from light, heat, heavy metal and peroxide contamination, and excessive exposure to air. Formulating the product at low pH is preferable if the product is stable and soluble at low pH. Common antioxidants are shown in Table 7. The most widely used agent is sodium bisulfite because its oxidation-reduction potential lies in the range at which it does not preferentially oxidize too slowly or too rapidly. Other sulfurous acid salts also are effective antioxidants, as are ascorbic acid and sodium ascorbate. Sometimes, combinations of antioxidants strengthen oxidative drug protection as well as the combination of an antioxidant and a chelating agent. The most common chelating agent used in parenterals is disodium ethylenediaminetetraacetic acid (DSEDTA).

Table 6 Common buffer systems used in small-volume parenteral products

pH	Buffer system	Concentration (%)
3.5–5.7	Acetic acid–acetate	1–2
2.5–6.0	Citric acid–citrate	1–5
6.0–8.2	Phosphoric acid–phosphate	0.8–2
8.2–10.2	Glutamic acid–glutamate	1–2

Protein Stabilizers

Therapeutic proteins and peptides have exploded on the pharmaceutical scene in recent years. There are at least 30 commercial protein products currently marketed and hundreds more in clinical study. Proteins are very reactive

Table 7 Antioxidants commonly used in small-volume parenterals

Antioxidant	Concentration range (%)
Water soluble	
Sulfurous acid salts	
Sodium bisulfite	0.05–1.0
Sodium sulfite	0.01–0.2
Sodium metabisulfite	0.025–0.1
Sodium thiosulfate	0.1–0.5
Sodium formaldehyde sulfoxylate	0.005–0.15
Ascorbic acid isomers	
L- and D-Ascorbic acid	0.02–1.0
Thiol derivatives	
Acetylcysteine	0.1–0.5
Cysteine	0.1–0.5
Thioglycerol	0.1–0.5
Thioglycolic acid	
Thiolactic acid	
Thiourea	0.001–0.05
Dithiothreitol	
Glutathione	
Oil soluble	
Propyl gallate	0.05–0.1
Butylated hydroxyanisole	0.005–0.02
Butylated hydroxytoluene	0.005–0.02
Ascorbyl palmitate	0.01–0.02
Nordihydroguaiaretic acid	0.01–0.05
α -Tocopherol 9	0.05–0.075

with their environment, with such reactions causing protein degradation. In pharmaceutical dosage forms, proteins are potentially quite reactive with water, formulation components, packaging components, and air. Environmental conditions that promote protein degradation include high temperature, pH excursions, light, oxygen, moisture, and mechanical stress. Degradation reactions are both chemical and physical, with physical stabilization often more challenging than chemical stabilization. Proteins easily aggregate under a variety of conditions, particularly at temperature extremes and with excessive mechanical manipulations. Denaturation in the form of aggregation can occur during the freezing and/or drying and subsequent storage of proteins processed by lyophilization. A number of ingredients have been shown to stabilize proteins both in the solution state and in the dry state (31–34). Serum albumin will compete with therapeutic proteins for binding sites in glass and other surfaces and minimizes loss of the protein caused by surface binding. With concern about viral contamination in natural substances like albumin, other competitive

binding agents are being investigated (e.g., hetastarch). A number of different types of substances are used as cryoprotectants and lyoprotectants to minimize protein denaturation during freeze-drying. Primary examples include amino acids (glycine, lysine, glutamine); polyhydric alcohols (sorbitol, glycerol, polyethylene glycol); nonreducing sugars (sucrose, trehalose); and polymers such as polyvinylpyrrolidone, methylcellulose, and dextran. Surface active agents, such as polysorbate 80, polysorbate 20, and poloxamer 188 (Pluronic 68), are widely used to minimize protein aggregation at air/water and water/solid interfaces. Buffers, antioxidants, and chelating agents also are used to stabilize proteins in solution when necessary.

Tonicity Adjusters

A variety of agents are used in sterile products to adjust tonicity. Most common are simple electrolytes such as sodium chloride or other sodium salts and nonelectrolytes such as glycerin and lactose. Tonicity adjusters are usually the last ingredient added to the formulation after other ingredients in the formulation are established and the osmolality of the formulation measured. If the formulation is still hypotonic (i.e., <280 mOsm/kg as measured by a commonly used osmometer instrument), tonicity adjusting agents are added until the formulation is isotonic. If the formulation is hypertonic, the degree of hypertonicity and the intended route of drug administration need to be considered. For intravenous administration, hypertonicity values up to approximately 360 mOsm/kg are not considered harmful. However, for other routes of administration, efforts should be made to make the final product isotonic before administration. This can be accomplished either by reducing concentrations of ingredients, if acceptable, or by diluting the product before administration.

Other Ingredients

Bulking agents are used in freeze-dried preparations to increase the solid content of the “plug” in the container after the sublimation process during the freeze-drying cycle. Bulking agents not only serve to enhance the elegance of the product but also can serve as stabilizers in adsorbing excess moisture during shelf life. Suspending agents keep the drug suspended in the solvent after shaking and allow homogeneous dosing of the suspended drug from the container. Emulsifying agents lower the interfacial tension of an oil and water interface to allow the two immiscible solvents to mix and form a stable emulsion

dosage form. Semisolid agents aid in the dispersibility of the drug in ophthalmic ointments and provide the ointment base. Examples of these different additives are:

1. *Bulking agents*: mannitol, lactose, sucrose, dextran
2. *Suspending agents*: carboxymethylcellulose, methylcellulose, gelatin, sorbitol
3. *Emulsifying agents*: lecithin, polysorbate 80
4. *Ophthalmic ointment bases*: petrolatum

Two comprehensive references are available that list type and concentration of all excipients used in commercial sterile formulations that should be part of every sterile formulation scientist's library (34, 35).

PACKAGING

The packaging system obviously is an integral part of the parenteral product, providing long-term protection and maintenance of physical and chemical stability of the product formulation. Packaging can also be used as a drug delivery tool by providing more convenient delivery of the drug product (e.g., syringes, dual chamber vials) and offering better control of drug dosing (e.g., cartridges). Packaging is a major source of particulate contamination and can contribute to physical and chemical degradation of the product. Packaging constituents can leach into the product or the product can be adsorbed or absorbed. The primary types of packaging systems are glass, rubber, and plastic. Metal tubes for ophthalmic ointments are not addressed here. Primary SVI packaging systems include glass sealed ampuls, rubber closed vials, prefilled syringes, cartridges, and small- and large-volume bottles made either of glass or plastic.

Glass (36)

Glass used for parenteral products is classified as type I, type II, and type III (Table 8). Type I is the highest quality

grade, composed almost exclusively of borosilicate (silicon dioxide), making it chemically resistant to extreme acidic and alkaline conditions. Type I glass, although more expensive, is preferred for most parenteral products. Often, even type I glass must be surface treated with agents such as ammonium sulfate or silica dioxide to remove surface leachates. Type II glass is made of soda-lime glass but is treated with sodium sulfite or sulfide to neutralize surface alkaline oxides. Type III glass is untreated soda-lime glass. Type II glass generally is used for large-volume injectables and for small-volume products if the solution pH level is less than 7.0. Type III glass can only be used for oily solutions and dry powders. The USP (37) and other compendia provide requirements and tests necessary to qualify the different types of glass.

Formulation scientists must be aware that glass can and will leach out various elements such as boron, sodium, potassium, calcium, iron, and magnesium. Glass leachates can affect solution pH and cause precipitation problems if the drug or other formulation component forms insoluble salts when combined with these leachates. Solutions of high pH level are notorious for causing alkali leachates. Quality control of each lot of glass must be consistent to control these potential difficulties with leachates. Glass particulates can also be a problem owing to delamination of the inner surface of the glass.

Amber glass containers can be used for light-sensitive SVIs. The amber color is produced by the addition of iron and manganese oxides to the glass formulation. Oxide leachates can occur and catalyze oxidation reactions.

Rubber (38)

Rubber formulations are used as rubber closures (vials, cartridges); rubber plungers (syringes, cartridges); and other applications (rubber septum in dual chamber

Table 8 Glass used for small-volume parenterals

Type	General description	USP test	Size (ml)	Limits (ml of 0.02 N acid)
I	Highly resistant, borosilicate glass	Powdered glass	All	1.0
II	Treated soda-lime glass	Water attack	100 or less Over 100	0.07 0.2
III	Soda-lime glass	Powdered glass	All	8.5
NP ^a	General-purpose soda-lime glass	Powdered glass	All	15.0

^aFor nonparenteral articles.

Table 9 Autoclavable rubber compounds used in small-volume parenterals

Type	Additives	Water–vapor permeation	Potential reactivity with product
Butyl	Moderate	Low	Moderate
Natural	High	Moderate	High
Neoprene	High	Moderate	High
Polyisoprene	High	Moderate	Moderate
Silicone	Moderate	Very high	Low

vials, rubber septum for needle introduction in administration set tubing). The formulations can be very complex. Not only do they contain the basic rubber polymer, but also they may contain many additives such as plasticizers, fillers, vulcanizing agents, pigments, activators, accelerants, and antioxidants. Many of these additives are not fully characterized for content or purity and can be sources of physical and chemical degradation problems in parenteral products. The formulation scientist must work as closely with the rubber manufacturer as with the glass manufacturer to choose the appropriate rubber formulation having consistent specifications and characteristics to maintain product stability.

The most common rubber polymers used in SVI closures are natural and butyl rubber (Table 9). Silicone and neoprene also are used but less frequently in sterile products. Butyl rubber has great advantages over natural rubber in that butyl rubber requires fewer additives, has low water vapor permeation properties, and has good characteristics with respect to gaseous (e.g., oxygen) permeation and reactivity with the active ingredient.

Problems with rubber materials include leaching of constituents (e.g., zinc) into the product, adsorption of active ingredients or antimicrobial preservatives, and coring of the rubber by repeated insertion of a needle. Coring produces rubber particulates that affect the quality and, potentially, the safety of the product.

Siliconization of rubber closure is a common practice in manufacturing to facilitate movement of the closure through stainless steel equipment on the filling lines. However, silicone is incompatible with hydrophobic drugs. Excessive silicone on rubber can potentiate protein aggregation and cause precipitation problems with certain drugs. Elastomer manufacturers have developed rubber formulations with specially bonded coatings that provide “slippery” rubber surfaces and, thus, do not require the

need to apply silicone for high-speed processing equipment.

Plastic

Plastic packaging has always been important for ophthalmic drug dosage forms and is gaining in popularity for injectable dosage forms. Plastic bottles are used to enable people to apply droplets of medication into the eye. Plastic bottles for LVIs have been used for many years. Plastic vials for SVIs may be a wave of the future. Plastic packaging offers such advantages of cost savings, elimination of the problems caused by breakage of glass, and increase convenience of use. As with other packaging systems, plastic formulations can interact with the product, causing physical and chemical stability problems. Plastic formulations are less complicated than are rubber formulations and tend to have a lower potential for leachability of its constituents. However, plasticizer leachates are well-known with polymers such as polyvinyl chloride containers used for LVI bags and administration devices. The most commonly used plastic polymer for ophthalmic products is low-density polyethylene. For other SVIs, polyolefin formulations are widely used as well as polyvinyl chloride, polypropylene, polyamide (nylon), polycarbonate, and copolymers such as ethylene vinyl acetate.

STORAGE

Proper storage of SVIs is critical for the safety and potency of the active ingredient(s) contained in the packaging system. Long-term stability studies are necessary for the appropriate storage conditions. Stability studies involve storing the product at various temperatures, exposing to light, exposing to various relative humidities, and assessing the effect of mechanical stress

during transportation and handling. Studies on proper storage conditions and appropriate handling are extremely important in this age of global distribution of drug products, particularly products containing temperature- and stress-sensitive biomolecules. In addition to concerns regarding the maintenance of chemical and physical stability of the drug product during distribution and storage, there is also concern that the container-closure system is adequate to maintain sterility and other microbiological quality attributes of the sterile product. Container-closure integrity studies in recent years have taken on greater prominence as regulatory groups such as the FDA require these data in registration approvals and in the routine conducting of stability studies. Excellent references on container-closure integrity methods are available (39, 40).

DRUG DELIVERY—ORAL ROUTE

Brahma N. Singh

Kwon H. Kim

St. John's University, Jamaica, New York, U.S.A.

INTRODUCTION

Oral drug delivery is the most desirable and preferred method of administering therapeutic agents for their systemic effects. In addition, the oral medication is generally considered as the first avenue investigated in the discovery and development of new drug entities and pharmaceutical formulations, mainly because of patient acceptance, convenience in administration, and cost-effective manufacturing process. For many drug substances, conventional immediate-release formulations provide clinically effective therapy while maintaining the required balance of pharmacokinetic and pharmacodynamic profiles with an acceptable level of safety to the patient.

However, the potential for oral dosage form development is sometimes limited for therapeutic agents that are poorly absorbed in the gastrointestinal (GI) tract and unstable to various enzymes, in particular, to proteolytic enzymes, such as peptide and protein drugs. The overall process of oral delivery is frequently impaired by several physiological and pharmaceutical challenges that are associated with the inherent physicochemical nature of the drugs and/or the variability in GI conditions, such as pH, presence of food, transit times, expression of *P*-Glycoprotein (*P*-Gp) and CYP3A, as well as enzymatic activity in the alimentary canal. Manipulation of these problems and challenges is considered an important strategy for improving oral drug delivery, and requires thorough understanding and appropriate integration of physicochemical principles, GI physiology and biochemistry, polymer science, pharmacokinetics, and pharmacodynamics. Over the last 3 decades, much research effort has been made in this area to address various biological and technological issues. Research has opened many novel avenues for the more effective, sustained, or rate-controlled oral delivery of both existing and new therapeutic agents, including peptide and protein drugs emerging from the biotechnology arena.

Furthermore, the oral route offers an attractive approach of drug targeting at the specific sites within GI tract for the treatment of certain pathological conditions, such as gastroesophageal reflux disorder, gastroduodenal ulcers, inflammatory bowel disease, and stomach and

colon cancers. Oral drug delivery systems (DDS) can be classified into three categories: immediate-release (IR) preparations, controlled-release (CR) preparations, and targeted-release preparations. This chapter describes the recent technological advances in oral drug delivery and various physicochemical and biological barriers, and also provides some insight on future strategies to improve oral drug delivery.

ANATOMICAL AND PHYSIOLOGICAL CHARACTERISTICS OF THE GI TRACT

Mechanisms and Pathways of Drug Absorption

Orally administered drugs are mainly absorbed in the small intestine (duodenum, jejunum, and ileum) and in the large intestine (colon); however, other regions, such as buccal cavity, stomach, and rectum, also can be considered potential sites for drug absorption. The various anatomical and physiological characteristics of each segment are briefly described in Table 1.

Once at the surface of intestinal epithelium, a drug can be absorbed across by one or a combination of the following mechanisms: passive transcellular, passive paracellular, and carrier- and receptor-mediated transport systems. Paracellular transport involves the passage of drug molecules through aqueous pores created by epithelial tight junctions, and is the most likely route for polar, hydrophilic drugs since they exhibit poor membrane partitioning. In the human small intestine, the average size of these water-filled pores is approximately 7–9 Å for jejunum and 3–4 Å for ileum (2). In the colon, the estimated pore radii are about 8–9 Å, albeit this value was obtained from rat colon (3). Nevertheless, the extent of paracellular transport is limited as tight junctions comprise only about 0.01% of the total absorptive surface area of the intestine (villi) (4). Transcellular absorption involves the transport of drugs through the intestinal epithelial cells (enterocytes) and requires partitioning of drugs across both the apical and the basolateral membranes. Obviously, this route is mainly limited to the transport of relatively low molecular weight lipophilic drugs. Furthermore, studies in

Table 1 Anatomical and physiological characteristics of human GI tract

Region	Length (m)	Absorbing surface area (m ²)	Absorption pathways	Transit (or residence) time of solids (h)	pH		Enzymes and others	Microorganism (counts/g content)
					Fasted	Fed		
Stomach	0.2	0.1	P, C, A (?)	1–3	1.5–3	2–5	Pepsin, lipases, rennin, HCl, Cathepsin	10 ²
Small intestine	7	12.0		3–5				
Duodenum	0.3	0.1	P, C, A, F, I, E		5.5	5.0	Bile acids, trypsin, α-chymotrypsin and other peptidases, amylase, maltase, proteases, lipases, nucleases	10 ²
Jejunum	3.0	60	P, C, A, F, I, E		6.1	No change	Erepsin, amylase, maltase, lactase, sucrase, peptidases, lipases	10 ⁵
Ileum	4.0	60	P, C, A, F, I, E		7–8	No change	Enteropeptidase (enterokinase) and other peptidases, lipases, nucleases, nucleotidases	10 ⁷
Large intestine	1.5	0.3		4–16		No change		10 ¹¹
Cecum	0.06–0.07	0.05	P, C, A, E		5.7			
Colon	1.35	0.25	P, C, E		8.0		Reductases, esterases, glycosidases, amidases, sulfatase	10 ¹¹
Rectum	0.12				7.0			

P = Passive transport; C = Convective transport; A = Active transport; F = Facilitated transport; I = Ion pair transport; E = Endocytosis.
(From Ref. 1.)

humans have demonstrated that absorption by the transcellular route decreases significantly in the colon (small intestine > ascending colon > transverse colon), which has implications for delayed or sustained release formulations, whereas no such gradient exists for the paracellular route (5).

Carrier-mediated transport involves interaction of the drug with a specific transporter or carrier, in which drug is transferred across the cell membrane or entire cell and then released from the basal surface of the enterocyte into the circulation (6). The process is saturable and utilized by small hydrophilic molecules (7). Drugs that are shown to be transported by this mechanism include β -Lactam antibiotics, cephalosporins, and ACE inhibitors (7).

Receptor-mediated transport involves internalization of an external substance, which may be a ligand for which there is a surface bound receptor, or a receptor which binds to a surface located ligand (8). During this process, a small region of the cell invaginates and pinches off, forming a vesicle. This process, in general, is known as endocytosis and comprises phagocytosis, pinocytosis, receptor-mediated endocytosis (clathrin-mediated), and potocytosis (nonclathrin mediated) (9).

After a drug is absorbed in the GI tract, it can gain access to the systemic circulation via two separate and functionally distinct absorption pathways—portal blood and the intestinal lymphatics. The relative proportion of drug absorbed via these two pathways is largely dictated by physicochemical and metabolic features of the drug, and the characteristics of the formulation (10).

The portal blood represents the major pathway for the majority of orally administered drugs as it has higher capacity to transport both water soluble and poorly water soluble compounds (10). During this process, hydrophilic molecules are carried to the liver via the hepatic portal vein, and then by the hepatic artery gain across to the systemic circulation for subsequent delivery to their sites of action. On the other hand, highly lipophilic drugs ($\log P > 5$) that cross the same epithelial barrier are transported to the intestinal lymphatics, which directly delivers them to the vena cava, thereby bypassing the hepatic first-pass metabolism (10).

Gastrointestinal Motility

The process of GI motility occurs both during fasted and fed states; however, the pattern differs markedly in the two states. In the fasted (interdigestive) state, the pattern is characterized by a series of motor activities known as interdigestive myoelectric cycle or migrating motor complex (MMC), which usually occurs every 80–120 min. Each cycle consists of four consecutive

phases (11, 12). Phase I (basal state) is a quiescent period of about 45–60 min without any contractions, except for rare occasions. Phase II (preburst state) is a period of similar duration (30–45 min) that consists of intermittent peristaltic contractions that gradually increase in intensity and frequency. Phase III (burst state) is a short period that consists of large, intense peristaltic contractions, lasting about 5–15 min. This phase serves to sweep the undigested materials out of the stomach and for this reason, phase III contractions are known as “housekeeper” waves.

As phase III of one cycle reaches the end of the distal ileum (ileocecal junction), phase I of the next cycle begins in the stomach (proximal) or esophagus (lower esophageal sphincter). However, sometimes MMC may originate in the duodenum or jejunum and some MMC may not have action potentials strong enough to traverse through the entire small intestine (12). Phase IV is a brief transitional phase (0–5 min) that occurs between phase III and phase I of two consecutive cycles.

In the fed state, the onset of MMC is delayed. In other words, feeding results into delayed gastric emptying. The duration of this delay is mainly dependent on the size (light or heavy) and composition (fatty or fibrous) of the meals. Consequently, the fate of pharmaceutical dosage forms is mainly subject to the pattern of GI motility in fasted (or fed) state at the time of dosage administration.

PROBLEMS AND BARRIERS TO ORAL DRUG DELIVERY

The biggest problem in oral drug delivery is low and erratic bioavailability, which mainly results from one or more factors such as poor aqueous solubility, slow dissolution rate, low intestinal permeability, instability in GI milieu, high first-pass metabolism through liver and/or intestine variable GI transit, and *P*-gp mediated efflux. This, in turn, may lead to unreproducible clinical response or a therapeutic failure in some cases due to subtherapeutic plasma drug levels. Indeed, the incomplete and variable oral bioavailability will have its most serious impact for drugs with a narrow “therapeutic window” (13) (e.g., theophylline, carbamazepine, quinidine, etc.) From an economic point of view, low oral bioavailability results in the wasting of a large portion of an oral dose, and adds to the cost of drug therapy, especially when the drug is an expensive one (14). It is, therefore, extremely important that these issues be considered and a suitable technique (or an animal model) be used while estimating the contributions from each factor responsible for low and/or variable bioavailability.

Physicochemical Barriers to Oral Drug Delivery

Aqueous solubility

It has long been recognized that before an orally administered drug becomes available for absorption at specific sites within the GI tract, it must be dissolved in the GI fluid. Since both the dissolution rate and the maximum amount of a drug that can be dissolved are dictated by the solubility of the drug in the medium (15), aqueous solubility of a drug could be regarded as a key factor responsible for low oral bioavailability of poorly water-soluble drugs, thereby limiting their therapeutic potential. Other issues related to low bioavailability for a sparingly soluble drug are lack of dose proportionality, substantial food effect, high intra- and intersubject variability, gastric irritancy, and slow onset of action (16). These problems are further exacerbated when attempts are made to develop CR dosage forms (17). Unfortunately, many potent compounds, including new chemical entities (NCEs), possess very low aqueous solubility at physiological pH, which could be attributed to their high inherent lipophilicity incorporated by drug design in order to ensure good absorption (18). Consequently, various approaches are utilized to improve aqueous solubility, which mainly include chemical modification (19), complexation (17, 20, 21), micronization (22), solubilization using surfactants, solid dispersion (23, 24), and design of drug delivery systems. However, there may be specific practical limitations to each of these approaches. For instance, the salt formation approach is not feasible for neutral compounds, and in many cases also for weakly acidic or weakly basic drugs because of the reconversion of salts into aggregates of their corresponding free acid or base forms (23). This precipitation effect would thus lead to slower dissolution rates and may cause failure of a clinical response or epigastric distress due to change in pH (24). Sometimes, the rate of renal excretion may also increase, particularly when amine drugs are solubilized as acid salts (25).

Similarly, the commercial success of solid dispersion has been limited due to use of higher temperatures ($>100^{\circ}\text{C}$) or harmful organic solvents, such as chloroform or dichloromethane, which may result in chemical decomposition of drugs and carriers or possible toxicity from the residual solvent. These unacceptable problems led scientists to explore novel alternatives, particularly the cogrinding method, which involves cogrinding of a poorly water-soluble drug with a water-soluble polymer, such as polyvinyl pyrrolidone, polyethylene glycol (PEG), hydroxypropyl cellulose, hydroxypropylmethyl cellulose, polyvinyl alcohol (26, 27), or sugars such as D-Mannitol (28). These authors suggest that although the composition of the coground mixture is similar to that of solid

dispersions, supersaturation is maintained for a long period due to better dispersion through particle size reduction.

Lipophilicity

The lipid solubility or lipophilicity of drugs has long been recognized as a prerequisite for transcellular diffusion across the intestinal membrane. Traditionally, the lipophilicity of drug substances is expressed as the apparent partition coefficient or distribution coefficient ($\log P$) between *n*-octanol and an aqueous buffer (pH 7.4), which is pH-dependent in the case of ionizable compounds (29). In general, compounds with low $\log P$ are poorly absorbed, whereas compounds with $\log P > -1$ offer satisfactory absorption (29). It is important, however, that the drug possess an optimum lipophilicity, as too low or too high lipophilicity may result in less than optimum oral bioavailability. For example, Mori et al. (30) did not observe any significant improvement in oral absorption of disodium cromoglycate ($\log P < -3$) despite the fact that lipophilicity was increased by derivatization to a lipophilic (diethyl) ester prodrug ($\log P = 1.78$). This observation was attributed to a marked decrease in the water solubility (from 195.3 mg/mL to 0.0052 mg/mL), which occurred simultaneously with increased lipophilicity. Similarly, Wils et al. (31) reported for the first time that high lipophilicity ($\log P > 3.5$) decreases drug transport across the intestinal epithelial cells and could be accounted for loss of in vivo biological activity. The “cut-off” point of P value, that is, the P value corresponding to an optimal transepithelial passage of drugs, was found to be around 3000. Other consequences of high lipophilicity may include passive exsorption (32), and increased plasma protein binding and biliary excretion; the biliary excretion may limit the oral bioavailability of polypeptides.

Aqueous boundary layer

The aqueous boundary layer or the unstirred water layer (UWL) is a more or less stagnant layer, about 30–100 μm in thickness, composed of water, mucus, and glycocalyx adjacent to the intestinal wall that is created by incomplete mixing of the luminal contents near the intestinal mucosal surface (33). The glycocalyx is made up of sulfated mucopolysaccharides, whereas mucus is composed of glycoproteins (mucin), enzymes, and electrolytes. Until recently, the resistance of the UWL to intestinal absorption was believed to be correlated to the effective intestinal permeability (P_{eff}) values of the solutes; however, considerable evidence suggests instead that the available surface of the apical membrane of the intestinal mucosa is the main barrier for both actively and passively absorbed solutes (33). It is also interesting to note that coadministration of food and prokinetic (motility inducing)

agents such as cisapride tends to decrease the thickness of UWL by increasing segmental and propagative contractions respectively, which may have implications for drug dissolution in the GI tract (34). The reverse is true for some viscous soluble dietary fibers, such as pectin, guar gum and sodium carboxymethylcellulose, which may increase the thickness of UWL by reducing intraluminal mixing (35–37) and could possibly decrease the intestinal exsorption of lipophilic drugs like quinidine and thiopental (38).

Biological Barriers to Oral Drug Delivery

Intestinal epithelial barrier

The intestinal epithelial layer that lines the GI tract represents the major physical barrier to oral drug absorption. Structurally, it is made up of a single layer of columnar epithelial cells, primarily enterocytes and intercalated goblet cells (mucus secreting cells) joined at their apical surfaces by tight junctions or zonula occludens. These tight junctions are formed by the interaction of membrane proteins at the contact surfaces between cells and are responsible for restricting the passage of hydrophilic molecules during the paracellular transport. In fact, electrophysiological studies have suggested that epithelium gets tighter as it progresses distally, which has been implicated in a reduced paracellular absorption in the colon (39).

The epithelium is supported underneath by lamina propria and a layer of smooth muscle called muscularis mucosa (3–10 cells thick). These three layers, i.e., the epithelium, lamina propria, and muscularis mucosa, together constitute the intestinal mucosa (40). On the apical surface, the epithelium along with lamina propria projects to form villi. The cell membranes of epithelial cells that comprise the villi contain uniform microvilli, which give the cells a fuzzy border, collectively called a brush border. These structures, although greatly increase the absorptive surface area of the small intestine, provide an additional enzymatic barrier since the intestinal digestive enzymes are contained in the brush border. In addition, on the top of the epithelial layer lies another layer, the UWL, as previously described. The metabolic and biochemical components of the epithelial barrier will be discussed.

Gastrointestinal transit

Advanced CR dosage forms can provide a precise control over release rates or release patterns for most drugs, which is attractive from a clinical point of view, particularly minimization of peak and trough variations in plasma drug concentration, and chronotherapy. For example, the GI

therapeutic system (GITS[®], Alza Corporation) can provide zero-order drug absorption, in which the rate of drug absorption from the GI tract is constant and not determined by the amount of drug available in the GI tract. However, none of the CR systems can control the extent of drug absorption from the GI tract. This is mainly attributed to the fact that the extent of drug absorption from different regions of the GI tract is different, which in fact partly constitutes a basis for the biopharmaceutic classification scheme for drugs administered as extended-release (ER) products (41). Thus, indirectly the extent of absorption is determined by the GI transit time (GITT) of the dosage form rather than its CR properties or delivery program (42). In general, the GITT of most drug products is relatively short (8–12 h), which in turn impedes the formulation of a once daily dosage form (43).

From the oral delivery standpoint, both gastric emptying time (GET) and small intestinal transit time (SITT) are considered important since the majority of drugs are preferentially absorbed in the upper parts of the GI tract (stomach, duodenum, and jejunum). Moreover, the stomach and intestines have a limited site for drug absorption. This is known as an “absorption window.” The relatively short GET (1–3 h) and SITT (3–5 h) thus provide limited time for drug absorption through the major absorption zone. These problems are further aggravated by the highly variable nature of the gastric emptying process, which can vary depending on several physiological factors, such as food, age, posture, exercise, body mass index, circadian rhythm, etc.; pathological factors, such as stress, diabetes, Crohn’s disease, and motility disorders; and pharmaceutical factors, such as size and density of formulation and coadministration of drugs like anticholinergic and prokinetic agents. It is apparent that GI transit is less likely to be a critical determinant of bioavailability for drugs that are completely absorbed from the GI tract and if their dosage forms reside in the GI tract for a considerable period of time (~14–18 h).

Since SITT has been demonstrated to be constant and practically independent of food as well as physical properties of the releasing units, such as size and density (44), the variability in overall GITT is mainly contributed by gastric emptying. The variability in turn may lead to unpredictable plasma drug levels, and could severely impair the performance of pulsed- or time-release devices, which are basically designed to deliver drug after a predetermined time to a specific site of the GI tract. For instance, if there is a large intrasubject variation in transit times, then the use of time-release systems may be precluded due to the unintended delivery of drug to an inappropriate region of the GI tract (45).

Food effect

The coadministration of drugs with food is known to result in decreased, delayed, increased, or accelerated drug absorption, which may have pharmacokinetic and pharmacodynamic implications (46). Most often, the food effect is nonspecific and manifested as an interplay between physiological effects of food (such as delayed gastric emptying, stimulated bile secretion, increased liver blood flow, and alterations in gastric and duodenal pH), physicochemical characteristics of the drug (e.g., water solubility), or its formulation (e.g., size, structural organization, and dissolution profiles). In general, drugs that are most influenced are those that are primarily absorbed from the upper regions of the GI tract and/or are poorly water-soluble. Apparently, food does not have a clinically significant effect on the absorption of moderately soluble drugs having a pH-independent solubility, and those that are completely absorbed (e.g., glipizide, isosorbide-5-mononitrate, felodipine, and nifedipine) from the GI tract. Furthermore, food may indirectly influence the drug absorption by affecting drug release from both hydrophilic matrix as well as lipid matrix formulations. In the former case, the effect has been attributed to increased hydrodynamic mechanical stress, which is caused by increased gastric motility (47). In the latter, the effect is due to increased pancreatic and biliary secretions, which in turn affect the integrity of matrix (48).

Other potential factors that affect oral delivery are pH of the upper GI tract (49), which varies as a function of age, food and certain disease states, circadian rhythm (50, 51), various diseases of the GI tract (49), and drug–drug interactions (7).

Metabolic and Biochemical Barriers to Oral Drug Delivery

Presystemic metabolism

Orally administered drugs are subject to presystemic metabolism, which is comprised of three subtypes of mechanisms:

1. Luminal metabolism. This may be triggered by digestive enzymes secreted from the pancreas (amylase, lipases, and peptidases including trypsin and α -chymotrypsin), and those derived from the bacterial flora of the gut, especially within the lower part of the GI tract.
2. First-pass intestinal metabolism. This includes brush border metabolism and intracellular metabolism. The former occurs at the surface of the enterocytes by the enzymes present within the brush border membrane.

Furthermore, the brush border activity is generally greater in the proximal small intestine (duodenum \approx jejunum $>$ ileum \gg colon) and involves enzymes such as alkaline phosphatase, sucrase, isomaltase, and a considerable number of peptidases (7).

The intracellular metabolism occurs in the cytoplasm of enterocytes and involves the major class of phase I metabolizing enzymes (i.e., cytochrome P450s, in particular CYP3A4), several phase II conjugating enzymes, and others such as esterases. Important examples of intestinal phase II metabolism include sulfation of isoproterenol and terbutaline, and glucuronidation of morphine and propofol (52). It is obvious that intestinal epithelium as a site of preabsorptive metabolism may significantly contribute to the low bioavailability of therapeutic peptides and ester type drugs like aspirin, although it could serve as a key site for targeted delivery of ester or amide prodrugs (52).

3. First-pass hepatic metabolism. As an absorbed drug reaches the liver through the portal circulation, a fraction of the administered dose is biotransformed before it reaches the systemic circulation. This is known as first-pass hepatic metabolism. In comparison with intestine, the liver dominates the process of first-pass metabolism for most drugs by virtue of its large mass, multiplicity of enzyme families present, and its unique anatomical position (13). However, this is not true for some drugs, such as terbutaline, in which case the sulfation occurs predominantly in the small intestine, as well as for midazolam, in which first-pass extraction by intestinal mucosa and liver appears to be comparable ($44 \pm 14\%$ versus $43 \pm 24\%$) (52). It is also important to emphasize here that efficiency of first-pass metabolism (both hepatic and intestinal) varies considerably among different animal species and human subjects, which should be taken into account when deriving the estimates of oral bioavailability, particularly in the case of poorly soluble drugs.

P-Glycoprotein and other efflux systems

In recent years, it has been recognized that *P*-Gp can significantly contribute to the barrier function of the intestinal mucosa. *P*-Gp is an integral membrane protein, about 170–180 kDa, encoded by the *MDR1* gene in humans and contains 12 putative transmembrane domains and two ATP binding sites (53). In the small intestine and colon, *P*-Gp is expressed almost exclusively within the brush border membrane of mature enterocytes, where it

acts as an energy-dependent drug efflux pump. Although *P*-gp appears to be distributed throughout the GI tract, its levels are higher in more distal regions (stomach < jejunum < colon) (54). Moreover, several studies have shown that *P*-Gp and CYP3A4 have similar substrate specificity [reviewed in Ref. (55)]. The colocalization of *P*-Gp and CYP3A4 in the mature enterocytes and their overlapping substrate specificity reasonably suggest that the function of these two proteins may be synergistic and appear to be coordinately regulated (56). Consequently, a greater proportion of the drug will be metabolized since the repetitive two-way kinetics (drug exsorption from the enterocyte into the lumen via *P*-Gp and reabsorption back into the enterocyte) will simply prolong the drug exposure to CYP3A4 (57). This mechanism not only limits the absorption of a wide variety of drugs, including peptides, but also poses a threat for potential drug interactions when attempts are made to inhibit CYP3A4 or *P*-Gp (58). Other mechanisms of drug efflux process may involve organic cation and anion transporters, which have been described elsewhere (32).

CURRENT TECHNOLOGIES IN ORAL DRUG DELIVERY

Over the last 3 decades, many novel oral drug therapeutic systems have been invented along with the appreciable development of drug delivery technology. Although these advanced DDS are manufactured or fabricated in traditional pharmaceutical formulations, such as tablets, capsules, sachets, suspensions, emulsions, and solutions, they are superior to the conventional oral dosage forms in terms of their therapeutic efficacies, toxicities, and stabilities (59). Based on the desired therapeutic objectives, oral DDS may be assorted into three categories: immediate-release preparations, controlled-release preparations, and targeted-release preparations.

Immediate-Release Preparations

These preparations are primarily intended to achieve faster onset of action for drugs such as analgesics, antipyretics, and coronary vasodilators (17). Other advantages include enhanced oral bioavailability through transmucosal delivery and pregastric absorption (60), convenience in drug administration to dysphagic patients, especially the elderly and bedridden, and new business opportunities (61). Conventional IR formulations include

fast disintegrating tablets and granules that use effervescent mixtures, such as sodium carbonate (or sodium bicarbonate) and citric acid (or tartaric acid), and superdisintegrants, such as sodium starch glycolate, croscarmellose sodium, and crospovidone. Current technologies in fast-dispersing dosage forms include modified tableting systems, floss or Shearform technology, which employs application of centrifugal force and controlled temperature, and freeze drying (61). Some of these technologies are briefly described in Table 2.

Controlled-Release Preparations

The currently employed CR technologies for oral drug delivery are diffusion-controlled systems, solvent-activated systems, and chemically controlled systems (63). Diffusion-controlled systems include monolithic and reservoir devices in which diffusion of the drug is the rate-limiting step, respectively, through a polymer matrix or a polymeric membrane. Solvent-activated systems may be either osmotically controlled or controlled by polymer swelling. Chemically controlled systems release drugs via polymeric degradation (surface or bulk matrix erosion) or cleavage of drug from a polymer chain (63). Recent examples of commercial products that have been developed based on these CR principles are provided in Table 3. It is worth mentioning here that the so-called programmed-release (“tailored-release”) profile of a final CR product is rarely the outcome of a single pharmaceutical principle. Depending on the specific physicochemical properties of the drug in question and desired therapeutic objectives, different formulation and CR principles may be proportionally combined within the same dosage form. This task appears to be simpler when realized in terms of appropriate selection of polymers and excipients that incorporate desired principles.

Targeted-Release Preparations

Site-specific oral drug delivery requires spatial placement of a drug delivery device at a desired site within the GI tract. Although it is virtually possible to localize a device within each part of GI tract, the attainment of site-specific delivery in the oral cavity and the rectum is relatively easier than in the stomach and the small and large intestines. The latter requires consideration of both longitudinal and transverse aspects of GI constraints (66). Some of the potential CR and site-specific DDSs will be described.

Table 2 Immediate release preparations for oral delivery

Technology owner and DDS	Brief description	Unique features	Marketed products (drugs)
<i>Elan Corporation, plc, Dublin, Ireland:</i> EFVDAS [®]	Effervescent drug absorption system. A technology that allows development of user friendly formulations which, in turn allows for ease of administration and fast onset of action.	Ability to incorporate high drug loading within the one dosage form, which also facilitates development of combination dosage forms.	Ibuscent [®] (Ibuprofen) as an effervescent formulation
<i>Prographarm Group, Paris, France:</i> Flashtab [®] (62)	A tablet formulation consisting of micronized drug particles coated with Eudragit [®] E	Ability to offer rapid dissolution in saliva, taste masking, and tailored pharmacokinetics for both OTC and prescription drugs.	Tachipima Flashtab [®] and Febrectol [®] (Acetaminophen or paracetamol)
<i>R.P. Scherer Corporation, MI, USA:</i> Zydis [®] System (60)	A freeze-dried, porous tablet that disintegrates instantaneously in the mouth, releasing the drug, which subsequently dissolves or disperses in the saliva.	Enhanced oral bioavailability and improved patient compliance through transmucosal delivery and pregastric absorption.	Maxalt-MLT [®] (Rizatriptan benzoate); Feldene Melt [®] (Piroxicam); Claritin [®] Reditabs TM (Loratadine); Innovace Melt [®] and Renitec RPD [®] (Enalapril); Zofran [®] (Ondansetron); Zelapar [®] (Selegiline); Zydis Apomorphine under clinical trial

Table 3 Controlled-release preparations for oral delivery

Technology owner and DDS	Brief description	Unique features	Marketed products (drugs)
<i>ALZA Pharmaceuticals, CA, USA:</i>			
Elementary osmotic pump	It combines a water-soluble drug and sometimes an osmotic agent in a monolithic core and delivers drug in solution form.	High, predictable delivery rates can be obtained independent of GI motility and the pH of luminal fluids.	Potassium chloride
OROS® Push-Pull System	It has separate osmotic and drug layers and delivers drug in solution or suspension form.	Ability to deliver drugs ranging from very low to high water solubility.	Procardia XL® and Adalat CR® (Nifedipine) as once daily tablets; Glucotrol XL® (Glipizide)
OROS Delayed Push-Pull System	A controlled onset extended release (COER-24™) system.	Ability to synchronize extended release characteristics with the circadian variation, thereby providing a protective effect during the periods of increased risk as well as throughout the dosing interval.	Covera-HS™ (Verapamil)
OROS Tri-Layer Push-Pull System	Multiple layers, enable patterned, pulsatile or delayed delivery of compounds.		
OROS Push-Stick System	Designed to deliver insoluble drugs that require high loading, with an optional delayed, patterned, or pulsatile release profile.		
OROS-CT	Colon-targeted delivery system for local or systemic therapy.	Ability to maintain a constant drug input in the colon for up to 24 h or to deliver drug over an interval as short as 4 h; Oral delivery of peptides and proteins.	Chronset®
OSMET®-CT	A miniature osmotic pump for use as a research tool in clinical studies.	The system can be used to study colonic absorption in humans prior to development of colon-specific delivery systems.	
L-OROS	An osmotic system designed to deliver lipophilic liquid formulations containing insoluble drugs or polypeptides.		
MOTS®	Mucosal oral therapeutic system. A CR osmotic system based on OROS push-pull technology to deliver drugs to the oral cavity for extended time periods.	Both topical and systemic therapy.	Nystatin

(Continued)

Table 3 Controlled-release preparations for oral delivery (*Continued*)

Technology owner and DDS	Brief description	Unique features	Marketed products (drugs)
<i>Duffar BV, Weesp, The Netherlands:</i> Gradient Matrix System (64)	A multiple-unit matrix system in which a positive concentration of drug is applied in the direction of the core of the matrix using a coating technique. In addition, an inert excipient (xylitol) is added with an inverse concentration gradient, thus avoiding the formation of a barrier layer at the outer surface of the device.	Zero order release for highly soluble drugs.	Acetaminophen, Mebeverine HCl.
<i>Elan Corporation, plc, Dublin, Ireland:</i> PHARMAZOME®	A multiparticulate drug delivery technology for producing CR and taste masked preparations such as liquids, suspensions, effervescent and chewable tablets, reconstitutable powders, and unit dose sachet or sprinkle systems.	Release from the PHARMAZOMES can be controlled to deliver the desired profile, i.e., immediate-release, controlled-release and/or delayed release.	Theo-Dur® (Theophylline) as a twice daily syrup and twice daily sprinkle formulation.
SODAS®	Spheroidal oral drug absorption system. A drug delivery technology for producing multiparticulate dosage forms (capsules or tablets) using CR beads.	Customized release rates to suit the individual drug delivery requirements of a drug; controlled absorption irrespective of the feeding state.	Cardizem® SR (Diltiazem HCl) as a twice daily formulation; Cardizem CD (Diltiazem HCl) as a once daily formulation; Verelan® (Verapamil) as a once daily formulation, Morphelan (Morphine) as a once daily formulation (under clinical trial).
<i>Pennwalt Corporation, NY, USA:</i> Pennkinetic™ System	The system combines CR principles of ion exchange with membrane diffusion. The system is made up of an ion-exchange polymer-drug complex as a core material, which is subsequently coated with ethylcellulose to form a water insoluble but permeable coating.	Release rates are relatively constant and unaffected by variable conditions of the GI tract. The system can be formulated in capsule form as well as suspensions.	Delsym® (Dextromethorphan), Corsym® (Chlorpheniramine) and Cold Factor 12® (Phenylpropanolamine).
<i>Skye Pharma AG, Muttens, Switzerland:</i> Geomatrix® Systems (65)	A multi-layer tablet technology, which consists of a hydrophilic matrix core containing the active ingredient, and one or two impermeable or semipermeable polymeric barrier layers applied on one (two-layered system) or both bases of the core (three-layer system) by film-coating or by compression coating.	Constant drug release with one soluble drug or with drugs of different water solubility for 24 h.	Dilacor® XR (Diltiazem HCl) as a once daily formulation; Diclofenac Ratiopharm® Uno (Diclofenac Na); Nifedipine as a once daily formulation.

Gastroretentive systems

Gastroretentive systems (GRDDS) are designed on the basis of delayed gastric emptying and CR principles, and are intended to restrain and localize the drug delivery device in the stomach or within the upper parts of the small intestine until all the drug is released. Various mechanisms (approaches) of achieving gastric retention include floatation or buoyancy (floating systems) (43), mucoadhesion (bioadhesive systems), sedimentation (high-density systems), expansion (swelling and expanding systems), and geometry (modified-shaped systems). Other approaches include coadministration of drugs or fatty acid salts, or sham feeding of indigestible (e.g., polycarbophil) or enzyme-digestible hydrogels (67) that convert the motility pattern of the stomach to a fed state.

Based on the previously published literature, applications of GRDDS may be summarized for several different drugs with various physicochemical and biopharmaceutical properties:

1. Drugs required to exert local therapeutic action in the stomach: misoprostol, 5-Fluorouracil, antacids and antireflux preparations, anti *Helicobacter pylori* agents, and certain enzymes.
2. Drugs exhibiting site-specific absorption in the stomach or upper parts of the small intestine: atenolol, furosemide, levodopa, *p*-Aminobenzoic acid, piretanide, riboflavin-5'-phosphate, salbutamol (albuterol), sotalol, sulpiride, and thiamine.
3. Drugs unstable in lower part of GI tract: captopril.
4. Drugs insoluble in intestinal fluids (acid soluble basic drugs): chlorthalidone, chlorpheniramine, cinnarizine, diazepam, diltiazem, metoprolol, propranolol, quinidine, salbutamol, and verapamil.
5. Drugs with variable bioavailability: sotalol hydrochloride and levodopa

The common objective in each case is to prolong, in a predictable manner, the overall GITT, which appears to be a major determinant of clinical efficacy of CR dosage forms. This can lead to improved bioavailability of drugs, especially those with limited absorption sites in the small intestine (class 2).

While employing this approach for enhancing oral bioavailability of poorly soluble drugs, in which drug absorption is dissolution-rate limited, the following considerations must be taken into account:

1. The optimization of prolonged gastric residence time (GRT) should be done in the light of dissolution time required to achieve complete dissolution in vivo. In other words, if the inherent physicochemical properties of the drug and biological environment of the

stomach allow for the complete dissolution of the required dose during the normal GRT, the gastroretentive approach is unlikely to offer any advantage.

2. The increase in dissolution rate due to the gastric retention does not automatically translate into an increased and less erratic bioavailability. This feature will rather depend on whether the rate and/or extent of drug absorption is limited primarily by dissolution when the GRDDS is administered, as it has been previously suggested for conventional dosage forms (34).

Additionally, since the stomach is one of the desired absorption sites for weakly acidic drugs, there should be no lag time in drug release from the GRDDS. Ideally, this type of delivery system is required for loop diuretics, such as furosemide and piretanide, in which the release of a certain amount of drug in the stomach is desired to obtain more balanced bioavailability (17). Consequently, this property prompted the development of floating systems for these acidic drugs (68, 69).

It is obvious that drugs such as nifedipine and both isosorbide-5-mononitrate and isosorbide dinitrate, which have nonspecific, wide absorption sites and so are well absorbed along the entire GI tract, may not be suitable candidates for GRDDS. Also, drugs that are irritant to the gastric mucosa (43) and those undergoing significant first-pass metabolism may have some limitations (1). Relevant examples of the latter type are nifedipine, propranolol, levodopa, diltiazem, metoprolol and 5-Fluorouracil.

Mucoadhesive systems (MADDS)

The term mucoadhesion is commonly used to describe an interaction between the mucin layer, which lines the entire GI tract, and a bioadhesive polymer, which could be natural or synthetic in origin (70). From the oral delivery standpoint, these systems are used to immobilize and localize a drug delivery device in the selected regions of the GI tract, which could be an oral cavity (buccal and sublingual routes), the esophagus, stomach, small intestine, or colon (oral route). For the most part, research in this area has focused on the design of polymeric micro- and nanoparticulate systems that use hydrophilic polymers, primarily due to their propensity to interact with the mucosal surface (71).

A review of recent studies indicate that mucoadhesion of polymers, especially hydrogels, involves a combination of surface and diffusional phenomena that contribute to the formation of "semipermanent" inter-chain bridges between the polymer and the mucosal

surface (72). The various proposed mechanisms of mucoadhesion include lowering of interfacial tension, interpenetration of the mucoadhesive polymer and mucin, formation of an electrical double layer at the adhesive/mucin interface, and formation of a hydrogen bond and/or van der Waals' forces of attraction (70).

Important advantages of MADDs include:

1. Intimate and prolonged contact of the drug delivery device with the absorbing membrane, which has the potential to maximize both the rate as well as the extent of drug absorption.
2. Prolonged and controlled GI transit of the dosage forms.
3. Site-specific drug delivery, which has the potential for local (topical) therapy of several conditions, such as aphthous stomatitis, gastric ulcer, esophageal cancer, toothache, and dental sores, as well as the potential for the treatment of systemic diseases such as diabetes mellitus and angina pectoris (73).
4. Potential for delivering drugs that undergo considerable first-pass metabolism through the liver (developed as buccal and sublingual MADDs).

Examples of marketed mucoadhesive formulations are Aftach[®] buccal tablets (triamcinolone acetonide), Susadrin[®] sublingual tablets (nitroglycerin; Forest Laboratories, NY), and Buccastem[®] buccal tablets (prochlorperazine maleate; Reckitt and Colman, England).

Enteric-coated systems

Enteric-coated systems (ECS) utilize polymeric coatings that are insoluble in the gastric media and therefore, prevent or retard drug release in the stomach. Various types of ionizable polymers are commercially available. They dissolve at various pH ranging between 4.8 and 7.2 (74). ECSs are generally applicable to four major types of drugs (75):

1. Drugs that are unstable in the gastric milieu. Examples include erythromycin, penicillin V, pancreatin, and insulin.
2. Drugs that are an irritant to the gastric mucosa and cause unpleasant side effects such as nausea and vomiting. Examples include aspirin and other NSAIDs (e.g., naproxen).
3. Suitable candidates for delayed-release ("time-controlled release") dosage forms, which provide a lag time between 3 and 4 h (74).
4. Drugs with site-specific absorption in the intestines.

Examples of commercial enteric-coated formulations include Ery-Tab[®] (erythromycin; Abbott), Prilosec[®]

(omeprazole; Astra Merck), Pancrease[®] (pancrelipase; McNeil Pharmaceutical), and Ecotrin[®] (aspirin; SmithKline Beecham) (76).

Colon-specific drug delivery systems

Colon-specific drug delivery systems (CSDDS) are designed to permit targeted drug release to the terminal ileum and proximal colon. The objective of delivering drugs to these parts of the GI tract is twofold. First, to provide local delivery for the treatment of colonic diseases, such as inflammatory bowel diseases (ulcerative colitis and Crohn's disease), colon cancer, local spasm of bowel, and constipation. Secondly, to deliver therapeutic peptides and proteins, such as insulin, calcitonin, vasopressin, cyclosporin A, nisin, and cytokine. In addition, drug delivery to the colon is also advantageous from the viewpoint of circadian biorhythms since it can provide a nocturnal release of drugs for diseases that are characterized by night-time or early morning onset (asthma, hypertension, arthritis, cardiac arrhythmias, etc.) (77).

Currently, four strategies are being pursued to achieve colon-specific drug delivery (78).

1. pH-controlled systems. These systems rely on the pH difference between the small and the large intestine. The approach involves coating drugs with pH-sensitive polymers such as Eudragit[®]. Commercial examples include Asacol[®] (mesalazine coated with Eudragit S; for pH ≥ 7), Salofalk[®], Claversal[®], and Mesasal[®] (mesalazine coated with Eudragit L-100; for pH ≥ 6).
2. Enzyme-controlled systems. These systems also are known as microbially controlled systems. They exploit the enzymatic activity of the colonic microflora and therefore, mainly use saccharide-containing polymers or azopolymers, which respectively undergo glycosidic degradation or azoreduction. Alternatively prodrug approach is utilized in which promoieties are resistant to hostile environment of stomach and small intestine, but are susceptible to degradation in the colon. Examples of such prodrug formulations include Dipentum[®] capsules (olsalazine sodium or azodisal sodium; Pharmacia and Upjohn), Colazide[®] tablets (balsalazide disodium; Salix Pharmaceuticals, Ltd., CA), and Intestinol[®] (bensalazine or bensalazide).
3. Time-controlled systems. These systems rely on the relatively consistent small intestinal transit time, which approximates between 3 and 5 h. Obviously, drug release from such systems occurs after a predetermined lag phase (i.e., ≥ 5 h), which can be

precisely programmed by adjusting the thickness and/or composition of the barrier (e.g., coating) formulation. Examples include TIME-CLOCK system ($t_{\text{lag}} = 8.85 \pm 0.90$ h) (79), Pulsincap[®] system ($t_{\text{lag}} = 5.40 \pm 2.53$ h) (80), Geomatrix[®] systems ($t_{\text{lag}} = 17.3$ h in fasted, 12.5 h in fed) (81), and Chronotopic[®] system ($t_{\text{lag}} = 5\text{--}6$ h) (82).

4. Pressure-controlled systems. These systems rely on the strong peristaltic waves in the colon that temporarily increase the luminal pressure.

STRATEGIES TO IMPROVE ORAL DRUG DELIVERY

Chemical Modification Approach

As a general rule, the design of orally active agents must account for the effects of structural modifications on water solubility, lipophilicity, stability (chemical or enzymatic) and therapeutic index. Prodrug design is a commonly used strategy to improve these drug properties. The term prodrug may be defined as a chemical derivative of a drug that is bioconvertible into the active parent drug or an active metabolite responsible for the therapeutic effect. It is important that the prodrug contain a “trigger” site so that its *in vivo* fate can be predicted and the rate of biotransformation can be controlled. Common examples of triggers include ester, amide, carbonate, carbamate, azo and glycosidic (for colon-specific delivery) bonds. In addition, the promoiety (progroup) should be pharmacologically inert, nontoxic, and readily excretable. From the oral delivery standpoint, the design of a prodrug should have following objectives:

1. To enhance the oral bioavailability of a drug. The improved systemic delivery of a drug could be attributed to the fact that a prodrug has the potential to circumvent barriers such as low GI permeability and significant first-pass metabolism (83).
2. To achieve a site-specific drug delivery through a target-specific bioactivation mechanism.

Both of these objectives are achievable provided the delivery (transport) properties of the drug are improved while maintaining its biological activity *in vivo*. In this context, the parent drug properties, such as lipid solubility, aqueous solubility, partition coefficient, and chemical and metabolic stability, are optimized, often in a “balanced” combination.

Based on the definition of a prodrug, the following classifications may be proposed for oral prodrugs:

1. Lipophilic prodrugs. These include slightly soluble salts (e.g., quinidine polygalacturonate, Cardioquin[®]), esters (e.g., enalapril, Vasotec[®]; ramipril, Altace[®]; lisinopril, Prinivil[®]), or complexes.
2. Water-soluble prodrugs. These include water-soluble salts, esters (e.g., fosphenytoin; Cerebyx[®]) or complexes.

The synthesis of lipophilic esters appears to be the most popular approach for improvement of drug lipophilicity, which may be largely attributed to the ubiquitous occurrence of esterases *in vivo* and their potential for enhanced drug absorption via the lymphatic route (10). Briefly, the approach involves either masking (or latentiation) of charged polar groups, such as carboxylic acids, phosphates, and others, or conjugation of lipophilic acyl groups with hydroxyl groups of the parent molecule (84). Once the prodrug is absorbed, it is hydrolyzed by esterases, whereby the parent drug is released.

In contrast to the previous approach, water-soluble prodrugs are formed by esterification of a drug's hydroxyl, amine, or carboxyl group with a promoiety designed to introduce an ionizable function or reduce intermolecular interactions responsible for low solubility (19). However, prior to the selection of an appropriate drug candidate, it is essential to ensure that the required therapeutic dose of the selected poorly water-soluble drug is sufficiently high enough so that the estimated time for its complete (*in vivo*) dissolution far exceeds the typical GI residence times (19).

Due to its higher water solubility, a soluble prodrug provides a greater concentration gradient (driving force) in the intestinal lumen for absorption as compared to its parent compound (19). The further fate of this prodrug would then be determined by the susceptibility of the hydrophilizing promoiety to various enzymes. For instance, if the promoiety were susceptible to cleavage by a membrane-bound brush border enzyme, the lipophilic and permeable parent drug would be released in the vicinity of the mucosal membrane and hence available for subsequent absorption (19). In another example, if the promoiety were susceptible to cleavage by enzymes secreted by the bacterial microflora of the lower GI tract, the lipophilic drug would be available for absorption through the colonic mucosa (85). Glycosidic and glucuronidic prodrugs that exploit bacterial glycosidases and glucuronidases, respectively, are examples of the latter case. Nevertheless, drug conjugates of natural cyclodextrins (ester type) are also known to be susceptible to bacterial enzymes; however, these conjugates are resistant to the gastric and intestinal enzymes. This finding prompted their evaluation as delayed release-type prodrugs for achieving colon-specific delivery (17).

Another interesting approach of improving the oral bioavailability is based on the design of a so-called prodrug of a prodrug (i.e., “pro-prodrugs” or “double prodrugs”). The approach involves protecting the benzylic phenol (or aniline) derivative with a functionality that can be predictably hydrolyzed (25). Obviously, the active drug is generated via an unstable intermediate in a two-step hydrolytic process. Most of the time, the first step is rate-determining and involves an enzymatic cleavage, whereas the second step is faster and involves a molecular decomposition of the intermediate (86). The strategy seems to increase the permeability of poorly soluble drugs, such as steroids, by several orders of magnitude (87).

Greenwald et al. (25) described a combination approach, which combines the concept of double prodrug and permeation enhancement by chemical conjugation with a hydrophilic polymer, PEG. The approach was found to be efficient in delivering an antitumor drug, daunorubicin. While not investigated by the authors of this study, this approach might also possess the potential to reverse multidrug resistance (MDR), in addition to providing high oral bioavailability and tumor selectivity. This statement could be partly supported by a recent finding that PEG-based surfactants can interfere with *P*-Gp substrate binding and thereby reverse MDR (88).

The design of oral prodrugs is not limited to the objective of increasing oral bioavailability and targeted drug delivery. Recently, Kimura et al. (89) described a novel concept of colon targeting for oral treatment of ulcerative colitis, while overcoming the systemic side effects of corticosteroids. The design involves synthesis of glycosidic prodrugs of an antedrug (“pro-antedrug”). Since the resulting pro-antedrugs were hydrophilic due to the polar nature of the promoity, they were not absorbable in the small intestine of guinea pigs. However, they could generate the corresponding antedrugs within the colon by the action of colonic bacteria. The antedrug was thus made available for its local pharmacological action at the colonic mucosa, and when it entered into the systemic circulation, it rapidly metabolized to an inactive metabolite, which results in no systemic effect. To achieve similar objectives, Bodor et al. (90) utilized a “soft drug” concept, in which a lead compound is modified so that the new active drug undergoes a predictable and controllable metabolism *in vivo* to nontoxic moieties after producing its therapeutic effect.

In another recent study, Otagiri et al. (91) described a new concept (“mutual prodrug” or “chimera drug”) in which two drugs with different pharmacological activities were conjugated in order to enhance pharmacological activity or to prevent clinical side effects while

maintaining their individual therapeutic roles and biopharmaceutical profiles. Occasionally, the prodrug approach has been used to develop oral ER dosage forms by preparing a salt or complex of drug that is slightly soluble in the GI fluids (92) and to shift the absorption site of a drug within the GI tract (93).

Use of prodrug strategies for improving oral delivery of peptides and peptidomimetics (e.g., β -Lactam antibiotics) has also received considerable attention in recent years due to the therapeutic potential of these compounds, and ubiquitous peptidases and esterases, respectively. Similar to the prodrugs of nonpeptides, the prodrugs of peptide and protein drugs are designed in light of their metabolic sensitivity to various enzymes (e.g., aminopeptidases, carboxypeptidases, dipeptidases, α -Chymotrypsin, etc.) in order to mimic the absorptive and metabolic characteristics of nutritional substrates. For the most part, this approach has focused on the modification of *N*-Terminal (e.g., amino acid ester approach). However, in order to broaden the applicability of this approach for clinical development of orally bioavailable peptides and peptidomimetics, it is necessary to incorporate structural features that permit the optimization of the pharmaceutical (e.g., solubility), biopharmaceutical (e.g., metabolic stability and membrane permeability), and pharmacological (e.g., receptor affinity) properties of the molecule (94).

Additional examples of commercial formulations of prodrugs for oral administration are Ceftin[®] (cefuroxime axetil; GlaxoWellcome, Inc.); Anzemet[®] (dolasetron mesylate; Hoechst Marion Roussel, Inc.); Trileptal[®] (oxcarbazepine; Novartis Pharmaceuticals Corporation), and Claritin[®] (loratadine; Schering-Plough Corporation).

Formulation Approaches

Use of absorption enhancers

The coadministration of absorption enhancers has long been recognized to enhance the intestinal permeability of several hydrophilic drugs, including peptides and proteins. A number of absorption enhancing agents are commercially available. These include bile salts, surfactants, fatty acids, salicylates, glycerides, chelating agents, and others. Although most of these enhancers have the ability to promote drug uptake, some absorption enhancers may have potential to cause mucosal damage and systemic toxicity, which warrant their safety evaluation prior to selection for formulation development. Ideally speaking, an enhancer of choice for oral delivery will be one that reversibly loosens the tight junctions or transiently increases the membrane per-

meability and that has a relatively higher benefit/risk ratio. To satisfy these interests, a pair of excellent review articles (95, 96) has appeared that are more complete in scope than is possible here.

Based on the routes of permeation, permeation enhancers may act via paracellular or transcellular route or a combination of both. As a common feature, most of the promising absorption enhancers increase drug transport primarily through the modulation of paracellular permeability (96) since transcellular drug transport is not the most likely route for passive diffusion of hydrophilic drugs, including peptides. These are commonly referred to as paracellular promoters, which basically increase the aqueous pore radius through a variety of mechanisms. For instance, EDTA acts as a paracellular promoter by depleting calcium and magnesium in the regions of the tight junction (3). Interestingly, a recent mechanistic study demonstrated that carbonating agents that are integral components of effervescent formulations could be regarded as paracellular promoters since the generated CO₂ might affect the structural integrity of the tight junction (97).

On the contrary, transcellular promoters have been reported to improve oral absorption through membrane perturbation (98). Most of them act on the intracellular lipids, in many cases by fluidizing, solubilizing, or reorganizing the phospholipid domains in the membrane, which causes disruption of the membrane integrity (99). A change in membrane fluidity may also occur primarily through the interaction between these enhancers and membrane protein. Examples of such enhancers are sodium salicylate and sodium caprylate (98). Interestingly enough, there is ample evidence to suggest that nonionic surfactants (e.g., Cremophor EL and Tween 80) may enhance the permeability of drugs through their inhibitory effect on the *P*-Gp-Mediated counter transport process (100, 101). Although the exact mechanism(s) of inhibition is not well understood, these surfactants might directly act on the *P*-Gp protein on the mucosal surface, thereby decreasing the drug efflux from the intestinal membrane (101), or by decreasing the membrane lipid fluidity (102).

Use of metabolism inhibitors

As described previously, the presystemic metabolism of drugs may occur via various mechanisms. It is obvious, therefore, that coadministration of a low bioavailable drug and its metabolism inhibitor, which can selectively inhibit any of the contributing processes, would result in increased fractional absorption and hence a higher bioavailability. In fact, this approach seems to be a

promising alternative to overcome the enzymatic barriers to oral delivery of metabolically labile drugs such as peptides and proteins.

Current novel approaches in this area include: 1) bioadhesive delivery systems that can reduce the drug degradation between the delivery system and absorbing membrane by providing an intimate contact to the mucosa; 2) CR microencapsulated systems that can provide simultaneous delivery of a drug and its specific enzyme inhibitor at the desired site for required period of time; and 3) immobilization of enzyme inhibitors on mucoadhesive delivery systems (103).

Interestingly, the intestinal wall metabolism may also be inhibited by coadministration of certain drugs and diet, which act by selectively inhibiting an enzyme present in enterocytes. An illustrative example is that of cyclosporine, which undergoes extensive intestinal metabolism, resulting in low bioavailability ranging between 30–40% (104). Studies have shown that coadministration of ketoconazole (105) and grapefruit juice (106), which contains the inhibitory components, can significantly decrease the presystemic metabolism (both act via selective inhibition of intestinal, not hepatic, CYP3A4) and consequently increase the oral bioavailability of cyclosporine. In a differential manner, however, ketoconazole moderately inhibits *P*-gp (55), whereas grapefruit juice activates *P*-Gp-mediated efflux of cyclosporine, which is a well characterized substrate of *P*-Gp, thereby partially counteracting the CYP3A4-inhibitory effects of grapefruit juice (107).

Similarly, the coadministration of a drug that can selectively inhibit an enzyme in the liver may lead to increased bioavailability of another drug. For example, coadministration of erythromycin can result in inhibition of hepatic metabolism and thereby significantly increase the oral bioavailability of cyclosporine (108). As a matter of fact, this attribute of erythromycin appears to be selective, which permits a noninvasive measurement of the *in vivo* hepatic CYP3A4 activity, popularly known as erythromycin breath test (109). Many examples also exist related to the effects of diet on hepatic first-pass metabolism that are discussed in detail elsewhere (110, 111). Accordingly, in our view, the dietary approach seems to justify as a prospective alternative to decrease presystemic metabolism, especially in terms of cost effectiveness and clinical acceptance for routine medical practice.

Ion pairing and complexation

The ion pairing approach involves coadministration of a hydrophilic or polar drug with a suitable lipophilic

counterion, which consequently improves the partitioning of the resultant ion pair (relatively more lipophilic) into the intestinal membrane. In fact, the approach seems to increase the oral bioavailability of ionizable drugs, such as atenolol, by approximately 2-fold (112). However, it is important that a counterion possess high lipophilicity, sufficient aqueous solubility, physiological compatibility, and metabolic stability (112). Some of the successful applications of this approach have already been described in previous reviews (14, 112) and therefore, will not be described any further here.

Complexation approach has been frequently used to increase the aqueous solubility of water-insoluble and slightly soluble drugs, and dissolution rate, both in an effort to increase oral bioavailability. However, in certain instances, the approach can be used to increase the drug stability, particularly esters, control drug release rates, improve organoleptic properties, and maximize the GI tolerance by reducing drug irritation after oral administration. Generally speaking, β -Cyclodextrins are potential carriers for achieving such objectives but other complexing agents, such as caffeine, sodium salicylate, sodium benzoate, and nicotinamide, may also be used. The enhancement in solubility by these aromatic and heterocyclic compounds occurs via a π -Electron related donor-acceptor mechanism (21), whereas β -Cyclodextrins are known to form inclusion complexes with nonpolar guest molecules in their central lipophilic cavity during which no covalent bonds are formed or broken (20).

It has been suggested that since β -Cyclodextrins are hydrophilic, they have the ability to keep the hydrophobic drug molecules in solution form, thereby increasing the drug availability at the surface of the GI mucosa (where the drug solution partitions into the membrane). This results in increased drug absorption; however, it is important that cyclodextrin concentration be optimum (20). Furthermore, the commercial availability of a large variety of cyclodextrin derivatives permits the design of advanced oral DDS. For instance, the hydrophilic and ionizable cyclodextrins can serve as potent drug carriers in the formulation of IR and delayed-release (DR) dosage forms, respectively, while hydrophobic cyclodextrins can be used to retard the release rate of water-soluble drugs such as diltiazem and isosorbide dinitrate (17). Some of the commercial formulations that employ complexation with β -Cyclodextrin are Brexin[®] tablets (piroxicam; Chiesi Farmaceutici SpA, Parma, Italy), Surgamyl[®] tablets (tiaprofenic acid; Roussel-Maestrelli, Italy) and Nitro-pen[®] sublingual tablets (nitroglycerin; Nippon Kayaku, Japan) (20).

Lipid-based formulations

Lipid-based formulations of poorly water soluble drugs offer large versatility for oral administration as they can be formulated as solutions, gels, suspensions, emulsions, self-emulsifying systems, multiple emulsions, microemulsions, liposomes, and solid dispersions (113).

Administration of a drug in a lipidic vehicle/formulation can enhance the absorption and oral bioavailability via a combination of various mechanisms (14, 114) that are briefly summarized as follows:

- Physicochemical—Enhanced dissolution and solubility
- Physiological—Slowed gastric emptying (hence increased time for dissolution and absorption), stimulated bile flow and secretion of pancreatic juice, bile salt micellar solubilization, increased membrane permeability of intestinal epithelium, increased uptake from the intestinal lumen into the lymphatic system, reduced intestinal blood flow, and decreased luminal degradation and first-pass metabolism through the GI tract and liver

As a matter of fact, the coadministration of a fatty (“hyperlipidic”) food also has been known to improve the bioavailability of many poorly absorbed drugs by a combination of these mechanisms (115).

Additionally, several recent studies suggest that lipids may affect the oral bioavailability of lipophilic drugs by modulating biochemical processes. For example, Barnwell et al. (116) found that coadministration of oleic acid increases the bioavailability of propranolol, a lipophilic drug. Based on their results, the authors proposed two possible explanations. First, oleic acid may promote lymphatic absorption of propranolol since it is known to activate lymph production. The avoidance of hepatic first-pass metabolism, therefore, led to increased bioavailability. Second, oleic acid may reverse the inhibition of lymph production caused by propranolol. This hypothesis was consistent with the previous findings (listed in Ref. 116) that several lipophilic drugs, including propranolol, inhibit protein kinase C (a key enzyme involved in cellular signal transduction which controls secretory events, including lymph production) and that oleic acid reverses inhibition of protein kinase C by propranolol.

Likewise, several other studies have demonstrated that certain lipidic formulations can act as effective modulators of *P*-Gp counter transport systems (88, 100, 117–119), which offers a qualitative explanation for enhanced drug transport in independently examined cases, for instance, increased bioavailability of cyclosporine when coadministered with water-soluble vitamin E (120, 121). Thus, a lipid-based formulation approach

may be considered as a cost-effective strategy for future oral drug therapy.

For the sake of completeness, it should be noted that certain lipidic excipients, such as hydrogenated castor oil (Cutina[®] HR), polyethoxylated castor oil (Cremophor[®] RH 40), stearic acid, glyceryl behenate (Compritol[®] 888; Gattefossé Corporation, USA), glyceryl monostearate, glyceryl palmitostearate (Precirol[®] ATO 5; Gattefossé Corporation, USA), and saturated polyglycolized glycerides (Gelucire[®]; Gattefossé Corporation, USA), could be used as hydrophobic carriers to develop SR/CR tablets, particularly for water-soluble drugs, such as diltiazem HCl (122) and phenylpropanolamine HCl (123), as well as other drugs, such as theophylline (124). However, fed conditions of the stomach are likely to affect the *in vivo* disintegration of such formulations (125), and therefore, appropriate recommendations with regard to meal timing must be made to assure reproducible drug absorption or clinical response. In fact, the effect seems to be significant with a high-fat meal, which increases the pancreatic and biliary secretions that would affect the lipid matrix of tablets (48, 124). In contrast, however, SR dosage forms that are formulated as an oily “semisolid” matrix system filled in hard gelatin capsules seem to offer prolonged drug response under the fed state, which could be attributed to delayed gastric emptying (both by food and oily vehicles) and resultant prolonged absorption phase (126).

Unfortunately, the number of commercial formulations is very limited, primarily because of stability and manufacturing problems encountered during large-scale production. The list includes Sandimmune Neoral[®] (cyclosporine A; Novartis AG, Switzerland), which contains a microemulsion concentrate and is available as soft gels and solutions, Sandimmune[®] (cyclosporine A; Novartis AG, Switzerland), which contains an emulsion concentrate, and lipid soluble vitamins. Both formulations of cyclosporine have self-emulsifying properties and spontaneously form an o/w microemulsion (particle size <0.15 μm) and an o/w emulsion, respectively in the aqueous fluids of the GI tract (127).

Although the discussion concerning potential of liposomes, niosomes, microemulsions, and solid dispersions for oral delivery is outside the scope of this chapter, the interested reader is referred to recently published reviews on these topics (23, 128–130).

Design of drug delivery systems

Ideally, the ultimate goal of a *de novo* oral DDS should be aimed at providing a desired therapeutic response that comprises a controlled onset, a required duration, and a

sufficient intensity while avoiding or minimizing potential adverse effects. In terms of delivery system design, this objective translates to an advanced DDS that can precisely control the rate, time, and/or site of drug delivery independently of normal physiological variables such as GI pH, digestive state of the GI tract, peristalsis, and circadian rhythm. While it is difficult to collate the information about all the oral DDS available worldwide, Tables 2–4 describe some of the potential and advanced DDS in the alphabetical order of companies that have developed these technologies.

ORAL DELIVERY OF PROTEINS AND MACROMOLECULES

In the past 2 decades, significant progress has been made in the oral delivery of peptides and proteins that has enabled scientists to deliver insulin, calcitonin, heparin, and several vaccines by oral route. As with conventional drugs, the oral delivery of peptides and proteins is subject to similar challenges and biological barriers. However, to a greater extent this is due to their higher metabolic sensitivity and other inherent properties such as hydrophilicity, charge, and large molecular weight (≥ 600 Da). Current approaches to improve oral delivery of peptides and proteins include prodrug design (18, 94), ion-pairing approach (133), microemulsions (134), particulate delivery systems using polymeric carriers (135), liposomes (128), and niosomes (130), and use of metabolism inhibitors (103) and absorption enhancers (136). Depending upon the physicochemical properties of the therapeutic agent and its intended site of delivery, these approaches may be combined in an effort to enhance the oral bioavailability or achieve targeted therapy. The latter objective, in particular, refers to targeting of Peyer’s patch M cells, which offers potential strategy for oral delivery of vaccines.

FUTURE OF ORAL DRUG DELIVERY

In the last 3 decades, the area of oral drug delivery has undergone unprecedented changes. This transition has been mainly driven by the increased understanding of pharmaceutical and biological constraints at the molecular/atomic level, increased generation of drug candidates, and emergence of several advanced technologies. Overall, the area has made significant technological advances not only in drug delivery aspects but also in various processing (fabrication) technologies, as recently

Table 4 Miscellaneous advanced and novel drug delivery systems for oral delivery

Technology owner and DDS	Brief description	Unique features	Marketed products (drugs)
<i>Cortecs International Ltd., Teeside, U.K:</i> Halo™ Drug delivery system (131)	Hepatic avoidance using lymphatic output oral DDS. A liver-bypass drug delivery system that promotes absorption redistribution of lipophilic drug from the hepatic portal blood supply to the lymphatic system, thereby avoiding first-pass liver metabolism.	Improved oral bioavailability of lipophilic drugs.	Propranolol, verapamil, nifedipine, diltiazem, metoprolol, nicardipine, or labetalolol.
<i>Elan Corporation, plc, Dublin, Ireland:</i> DUREDAS®	Dual release drug absorption system. A bilayer tableting technology that combines an immediate-release granulate and a CR hydrophilic matrix complex within the one tablet.	Two different release rates or dual release of one or two different drugs from a single dosage form.	
IPDAS®	Intestinal protective drug absorption system. A multiparticulate tablet technology that is composed of high density CR beads and an IR granulate.	Dosage form is highly flexible in that the release rate from the tablet can be customized to deliver a drug specific absorption profile associated with optimized clinical benefit and tolerability.	Naprelan (naproxen sodium) as a once daily formulation.
<i>Elan Corporation, plc, Dublin, Ireland:</i> INDAS®	Insoluble drug absorption system. A technology for improving the solubility and absorption characteristics of poorly water-soluble drugs, enabling the development of a CR formulation.	A well-maintained absorption of drug is consistently achieved over the 24-h dosing interval.	Nifelan® (nifedipine) as a once daily formulation.
MODAS®	Multiporous oral drug absorption system. A single-unit, immediate-release tablet formulation consisting of an inner core, containing active drug plus excipients, surrounded by a non-disintegrating, timed release coating.	Combination/dual release dosage forms with an immediate release outer coating.	Bron-12® (a 12-h multicomponent OTC cough cold product), potassium chloride (once daily).
BEODAS®	Bioerodible oral drug absorption system. A bioerodible micro/nano particle technology used in the development of oral protein and peptide formulations.	Oral administration of vaccines.	Under development.
PRODAS®	Programmable oral drug absorption system. A technology for producing multiparticulate formulations by encapsulating combinations of IR, delayed release and/or CR minitablets (1.5–4.00 mm in dia).	The hybrid system incorporates the benefits of both multiparticulate and single-unit monolithic systems into one dosage form.	Not available.

(Continued)

Table 4 Miscellaneous advanced and novel drug delivery systems for oral delivery (*Continued*)

Technology owner and DDS	Brief description	Unique features	Marketed products (drugs)
LOCIDAS [®]	Localized drug absorption system. A novel targeted oral drug delivery technology. The system uses targeting ligands, which are attached to coated microparticles of protein and peptide drugs. These are subsequently packaged in enteric-coated capsules that deposit the particles at appropriate sites of absorption within the GI tract.	Increased permeability and ultimate oral bioavailability of macromolecules.	Under development for insulin.
<i>F. Hoffmann-La Roche Ltd., Basel, Switzerland:</i> HBS TM	Hydrodynamically balanced system. A CR oral dosage form (capsule or tablet), which is designed to prolong the residence time within the stomach.	Increased time for dissolution, prolonged absorption phase, and improved pharmacokinetic profile.	Madopar HBS or Prolopa [®] HBS (L-dopa + Benserazide); Valrelease (diazepam).
<i>R.P. Scherer Corporation, MI, USA:</i> Pulsincap [®] System (132)	A unique CR (capsule) device that permits programmed drug release at a predetermined time and/or site within the GI tract (e.g., colon).	Allows sequential dosing of a patient at different predetermined times and/or sites in the GI tract, with same or different drugs.	Under development.
R.P. Scherer sol TM System	Liquid formulations for softgels, which incorporate the drug in a microemulsion preconcentrate or microemulsion form.	Oral delivery of proteins and peptides; enhanced oral bioavailability with reduced inter- and intraindividual variability in pharmacokinetics of certain drugs.	Sandimmune Neoral (cyclosporine).
<i>Yamanouchi Shaklee Pharma, CA, USA:</i> OCAS TM	Oral-controlled absorption system. A hydrophilic gel-forming oral CR system capable of providing predictable drug release and absorption up to 24 h throughout the GI tract, including the colon.	Applicable to wide range of drugs including small molecules and peptides; reduced food effect and intersubject variability in plasma drug levels.	None
CODES TM	A colon-targeted delivery system for proteins/peptides and other drugs. The system contains drug and lactulose as a core formulation, which is subsequently coated first with an enteric coating and then with a cationic polymer coating.		Insulin

reviewed (61, 137). Despite the fact that currently existing technologies have not been exploited in their full capacity, the annual sales of oral products always ranks first in the list of pharmaceutical products since they offer increased patient compliance and have greater therapeutic outcome. In addition, these technologies help pharmaceutical companies manage the life cycles of their products through extended patent protection. It is therefore anticipated that current trends in oral delivery will bring a much-awaited revolution in delivery of therapeutic agents, particularly biotechnology-based molecules.

SUMMARY

The oral route still remains the major and favorite route of delivery for most bioactive agents in many disease states, despite its challenges and limitations. Optimizing drug delivery potential through this route requires careful design of drug and its delivery system while taking into consideration the physicochemical properties of the drug, biological and metabolic barriers to oral delivery, pharmacokinetic principles, and patient-related critical variables. Consequently, combinations of different formulation and CR approaches may play a significant role in the potential development of oral DDS of existing and new lead compounds.

DRUG DELIVERY—ORAL COLON-SPECIFIC

Vincent H.L. Lee
Suman K. Mukherjee

University of Southern California, Los Angeles, California, U.S.A.

INTRODUCTION

Historically, oral ingestion has been the most convenient and commonly used method of drug delivery. For sustained- as well as controlled-release systems, the oral route of administration has received the most attention. This is because of greater flexibility in dosage form design for the oral rather than the parenteral route. Patient acceptance of oral administration of drugs is quite high. It is a relatively safe route of drug administration compared with most parenteral forms, and the constraints of sterility and potential damage at the site of administration are minimal.

Colon-specific drug-delivery systems offer several potential therapeutic advantages. In a number of colonic diseases such as colorectal cancer, Crohn's disease, and spastic colon, it has been shown that local is more effective than systemic delivery (1). Colonic drug delivery can be achieved by oral or by rectal administration. Rectal delivery forms (suppositories and enemas) are not always effective because a high variability is observed in the distribution of drugs administered by this route. Suppositories are effective in the rectum because of the confined spread and enema solutions can only be applied topically to treat diseases of the sigmoid and the descending colon. Therefore, the oral route is preferred. Absorption and degradation of the active ingredient in the upper part of the gastrointestinal tract is the major obstacle with the delivery of drugs by the oral route and must be overcome for successful colonic drug delivery.

Drugs for which the colon is a potential absorption site (for example, peptides and proteins) can be delivered to this region for subsequent systemic absorption. The digestive enzymes of the gastrointestinal tract generally degrade these agents. However, these enzymes are present in significantly lower amounts in the colon compared with the upper portion of the gastrointestinal tract (2).

Colon-specific drug delivery has been attempted in a number of ways that primarily seek to exploit the changes in the physiological parameters along the gastrointestinal tract (1, 3). These approaches include the use of prodrugs, pH-sensitive polymers, bacterial degradable polymers,

hydrogels and matrices, and multicoating time-dependent delivery systems. The use of these strategies to target drug delivery to the colon are addressed in detail.

ANATOMICAL, PHYSIOLOGICAL, AND BIOCHEMICAL CHARACTERISTICS OF THE COLON

In terms of size and complexity, the human colon falls between that of carnivores such as the ferret, which has no discernable junction between the ileum and colon, and herbivores such as the rat, which has a voluminous cecum. The cecum, colon ascendens, colon transversale, colon descendens, and rectosigmoid colon make up the colon. It is approximately 1.5 m long, with the transverse colon being the largest and the most mobile part (Fig. 1) (4). Unlike the small intestine, the colon does not have any villi. However, because of the presence of plicae semilunares, which are crescentic folds, the intestinal surface of the colon is increased to approximately 1300 cm² (3). The physiology of the proximal and distal colon differs in several respects that can have an effect on drug absorption at each site. The physical properties of the luminal content of the colon also change, from liquid in the cecum to semisolid in the distal colon.

The colon serves four major functions. They are: 1) creation of a suitable environment for the growth of colonic microorganisms such as *Bacteroids*, *Eubacterium*, and *Enterobacteriaceae*; 2) storage reservoir of fecal contents; 3) expulsion of the contents of the colon at a suitable time; and 4) absorption of water and Na⁺ from the lumen, concentrating the fecal content, and secretion of K⁺ and HCO₃⁻ (5). The active secretion of K⁺ is stimulated by mineralocorticoids.

The factors that affect absorption from the colon are given in Table 1. Colon-specific drug delivery is primarily dependent on two physiological factors. These are the pH level and the transit time.

The pH of the gastrointestinal tract is subject to both inter- and intrasubject variations. Diet, diseased state, and food intake influence the pH of the gastrointestinal fluid.

Fig. 1 Right, transverse, and left colon. (Adapted from Ref. 9.)

The change in pH along the gastrointestinal tract has been used as a means for targeted colon drug delivery (6). This can be achieved by using coatings that are intact at the low pH of the stomach but that will dissolve at neutral pH. The right, mid-, and left colon have pH values of approximately 6.4, 6.6, and 7.0, respectively (7). The pH of the colon is often lower than the pH of the small intestine, which can be as high as 8 or 9 (7). In vitro experiments simulating the pH of the different regions of the gastrointestinal tract suggest that drug release from delivery systems that are triggered by a change in pH might already occur in the small intestine (8). However, other studies have concluded the pH can be used for drug release in the colon (6). The contradictions may be a result of nonstandardized in vitro methods as well as attributable to the difference in drug properties and preparation methods of drug-delivery systems. Interspecies variability in pH is a major concern when developing and testing colon-specific delivery systems in animals and applying the information to humans (4).

Drug delivery to the colon via the oral route depends on the gastric emptying and small bowel transit time. Drugs taken before meals usually pass out of the stomach within

1 h, but can take up to 10 h if taken after a meal. The transit time in the small intestine is relatively constant, ranging between 3 and 4 h, regardless of various conditions such as physical state, size of dosage form, and presence of food in the stomach (9).

One of the major determinants of the absorption of a compound from the colon is residence in any particular segment of the colon. The time taken for food to pass through the colon accounts for most of the time the food is present in the gut. In healthy subjects, this is approximately 78 h for expulsion of 50% ingested markers but may vary from 18 to 144 h. Steady-state measurements of mean transit time after ingestion of markers for several days gave a mean transit time of 54.2 h (10).

When the dosage forms reach the colon, transit depends on size. Small particles pass through the colon (236 min for 3-mm tablets and 238 min for 6-mm tablets on study day 1; 226 min for 9-mm tablets and 229 min for 6-mm tablets on study day 2; 218 min for 12-mm tablets and 219 min for 6-mm tablets on study day 3) more slowly than the larger units (11). However, the density and size of larger single units had no real effect on colonic transit. It has been shown that pellets move faster than do tablets through the ascending colon and therefore may be more favorable than tablets with respect to colonic drug absorption (11).

Colonic transit time is only slightly affected by food but is reduced under stress. Studies have shown that drugs that act on the parasympathetic or sympathetic nervous system affect the propulsive motor activity, thereby influencing the colonic transit time (12). Although not significantly affected by most disease (13), the transit time is shorter in patients who complain of diarrhea and longer in patients with constipation.

PERMEABILITY AND METABOLIC CHARACTERISTICS

Drug Permeability in the Colon

Drug absorption in the colon is restricted by a number of barriers. The bacterial flora, which is significantly higher in the distal colon, can affect drug bioavailability (14). The mucus present at the epithelial surface of the colon acts as a physical barrier to uptake attributable to specific and nonspecific drug binding. Drug binding to the colonic lumen may facilitate enzymatic or environmental degradation by increasing the residence time of the drug. Cephalosporins, penicillins, and aminoglycosides are some of the small molecule drugs that bind to the negatively charged mucus (15). This binding can prevent

Table 1 Factors affecting drug absorption from the colon

1. Physical characteristics of drug (pK_a , degree of ionization)
2. Colonic residence time as dictated by gastrointestinal tract motility
3. Degradation by bacterial enzymes and byproducts
4. Selective and nonselective binding to mucus
5. Local physiological action of drug
6. Disease state
7. Use of chemical absorption enhancers, enzyme inhibitors, or bioadhesives

(From Ref. 8.)

drugs from reaching the epithelial surface as well. Some molecules such as carbachol and serotonin that stimulate mucus secretion can, therefore, reduce their own absorption as well as the absorption of any coadministered drug (16). The removal of this mucus barrier with mucolytic agents can result in increased absorption. Schipper et al. showed that chitosans had a pronounced effect on the permeability of mucus-free Caco-2 layers and enhanced the permeation of atenolol 10- and 15-fold (17). The binding of chitosan to the epithelial surface and subsequent absorption-enhancing effects were significantly reduced in mucus-covered HT-29-H cells. Alterations of this mucus layer, however, have been associated with pathological conditions.

The single most formidable barrier to the uptake of drugs occurs at the level of the epithelium (18). The lipid bilayer of the individual colonocytes and the occluding junctional complex (OJC) between these cells provide a physical barrier to drug absorption. OJC structures found at the apical neck of the cells in the gastrointestinal tract limit paracellular transport of water and small molecules (<350 Da) in a cation-selective manner (19). The movement of water and ions via the paracellular route is driven by transcellular ionic gradients, with the proximal colon appearing to be slightly more conducive to such activity than the distal colon (20).

Carrier-mediated absorption in the colon is not extensive and usually relates to the metabolic events in the residual bacteria (21). Drugs that pass from the apical to the basolateral side of this epithelial layer can do so either by the transcellular route (i.e., by passing directly through the colonocytes) or by the paracellular route (i.e., by passing through adjacent colonocytes). Mathematical models describing the transport of small drug molecules across these barriers have been developed (22). The movement of peptides is predominantly dependent on hydrogen bonding (23). Compared with peptides, proteins experience a greater thermodynamic barrier for passing through cell membranes and are more vulnerable to denaturation at the interface.

Drug molecules that have traversed the physical and enzymatic barriers of the colonic mucosa may enter either the blood capillary bed or the lymphatic sinuses. Intact drugs that reach the venous capillaries from the submucosa are transported to the liver via the hepatic-portal system where they may undergo significant metabolism. On the other hand, uptake into the lymphatic sinuses of the colon results in direct delivery into the systemic circulation that causes lesser metabolic breakdown of the absorbed drug (3).

Drug Metabolism in the Colon

Metabolic reactions in the liver and the small intestine are well documented (24). However, only sparse information is available on drug metabolism in the colon. Drug metabolism in the colon can be brought about by the host enzymes in the epithelial cells or by the microbial enzymes in the gut flora. Metabolic activities in the wall of the colon can be attributed to cytochrome P450, esterases, amidases, and various transferases (25). Reductive drug metabolism does not appear to be important at this site.

The colonic mucosa resembles the small intestinal mucosa with respect to the spectrum of metabolizing enzymes (26). However, the total metabolic capacity of the colonic wall is inferior, because the mucosal mass in the lower part of the intestine is several times smaller than that in the upper part. This may be more than offset by the high metabolic capacity found in the gut flora in the large intestine.

The gastrointestinal tract contains a variety of microorganisms that participate in the metabolism of ingested material (Tables 2 and 3) (27). The upper part contains only a small number of primarily gram-positive bacteria, whereas the colon contains a vast amount of primarily anaerobic bacteria, with *Bacteriodes*, *Bifidobacterium* and *Eubacterium* being the most common species found (28). Gram-positive cocci such as *Clostridium enterococci* and various species of *Enterobacteriaceae* are also present (29). The growth of the bacteria is regulated

Table 2 Drug metabolizing enzymes in the human colon that catalyze reductive reactions

Enzymes	Microorganism	Metabolic reaction catalyzed
Nitroreductase	<i>E. coli</i> , <i>Bacterioids</i>	Reduce aromatic and heterocyclic nitro compounds
Azoreductase	<i>Clostridia</i> , <i>Lactobacilli</i> , <i>E. Coli</i>	Reductive cleavage of azo compounds
N-Oxide reductase, sulfoxide reductase	<i>E. coli</i>	Reduce N-Oxides and sulfoxides
Hydrogenase	<i>Clostridia</i> , <i>Lactobacilli</i>	Reduce carbonyl groups and aliphatic double bonds

Table 3 Drug metabolizing enzymes in the colon that catalyze hydrolytic reactions

Enzymes	Microorganism	Metabolic reaction catalyzed
Esterases and amidases	<i>E. coli</i> , <i>P. vulgaris</i> , <i>B. subtilis</i> , <i>B. mycoides</i>	Cleavage of esters or amidases of carboxylic acids
Glucosidase	<i>Clostridia</i> , <i>Eubacteria</i>	Cleavage of β -glycosidases of alcohols and phenols
Glucuronidase	<i>E. coli</i> , <i>A. aerogenes</i>	Cleavage of β -glucuronidases of alcohols and phenols
Sulfatase	<i>Eubacteria</i> , <i>Clostridia</i> , <i>Streptococci</i>	Cleavage of <i>O</i> -sulfates and sulfamates

by gastric acids, peristaltic activity, and microbial interaction including bacterial metabolic byproducts. Administration of antibiotics as well as onset of disease and age can affect the metabolic activity of the intestinal microflora (30).

Redox reactions and hydrolysis are the predominant metabolic conversions triggered by the intestinal microflora. The primary reductive enzymes produced by the intestinal microflora are nitroreductase, deaminase, urea dehydroxylase, and azoreductase. The hydrolytic enzymes are β -glucuronidase, β -xylosidase, β -galactosidase, and α -L-arabinosidase. Studies conducted by Macfarlane and coworkers have shown that proteolysis can also occur in the colon (31). More recent findings by the group indicate that bacterial fermentation of proteins in humans could account for 17% of the short-chain fatty acids in the cecum and for 38% in the sigmoid and the rectum (32).

The unique enzymatic features of the microbial flora present in the colon make it conducive for drug targeting. Active metabolites intended for local therapy can be liberated from poorly absorbed parent molecules by microbial processes. An advantage can also be taken for release of drugs from delivery systems, disintegrating only by the action of microbial enzymes, as a means for targeted delivery. This approach is suitable for drug molecules that are unstable in the upper part of the gastrointestinal tract but can be absorbed from the lower part.

CHARACTERISTICS OF DRUGS THAT FAVOR COLONIC DELIVERY

The colon is a less hostile environment than the stomach and the small intestine (33). It has a longer retention time and is responsive to agents that cause an increase in the absorption of poorly absorbed drugs (34). Drugs that will benefit from colon targeting include those for the treatment of inflammatory bowel disease and irritable bowel syndrome. Drugs metabolized in the upper gastrointestinal

tract also would be candidates for colon targeting. Drugs such as theophylline, nifedipine, ibuprofen, diclofenac, metoprolol, brompheniramine, pseudoephedrine, dinitrate, isosorbide, oxprenolol, and low-molecular-weight peptides and peptide-like drugs have been shown to be effectively absorbed from the colon (35).

The permeability of the colonic epithelium may not be sufficient for achieving a transport rate required for therapeutic activity. This hurdle may be overcome, at least in part, by using penetration enhancers (Table 4). They include chelating agents, nonsteroidal anti-inflammatory drugs, fatty acids, and surfactants (36). Comparison of their rate of onset and recovery of a treated mucosa has also been made (37). Fatty acids have strong and fast reactivity and allow for a fast recovery of the barrier function. Bile salts and salicylates are moderate and fast-acting agents with fast barrier function recovery. Strong surfactants and chelators have strong or moderate reactivity and a slow recovery of barrier function. Solvents such as dimethylsulfoxide and ethanol have moderate reactivity and act primarily as agents to improve drug miscibility in an aqueous environment. The aforementioned enhancers are also effective in the small intestine (22). Some

Table 4 Some common colonic drug absorption enhancers

1. Nonsteroidal antiinflammatory agents (NSAIDs) (e.g., indomethacin and salicylates)
2. Calcium ion-chelating agents (e.g., EDTA and citrate)
3. Surfactants [e.g., polyoxyethylene lauryl ether (BL-9EX) and saponin]
4. Bile salts (e.g., taurocholate and glycocholate)
5. Fatty acids (e.g., sodium caprate, sodium caprylate, sodium laurate, and sodium oleate)
6. Mixed micelles [e.g., monoolein-taurocholate, oleic acid-taurocholate, oleic acid-polyoxyethylene hydrogenated castor oil (HCO 60) and oleic acid-glycocholate]
7. Other agents [e.g., acylcarnitine, azone (1-dodecylazacycloheptan-2-one), dicarboxylic acids and enamine]

enhancers that are more colon-specific include ethyl-acetoacetate, which must be first metabolically transformed to enamine (38).

Several chemical enhancers such as sodium ethylenediaminetetraacetate and sodium taurocholate, oleic acid (37), polyoxyethylated nonionic surfactants, citric acid, and dihydroxy bile salts open the paracellular route presumably by disruption of intracellular OJC function (37). The use of nitric oxide is another approach (39). Moreover, manipulation of the cyclooxygenase pathway activities to trigger the release of compounds like substance P may provide another means for altering colonic permeability (40).

Molecules such as sodium caprate, sodium caprylate, and sodium salicylate can enhance transcellular uptake of poorly permeable compounds through the colonic mucosa in low concentrations (41, 42). Some of these absorption enhancers can cause local irritation as well (43). It has been suggested that these enhancers might function to denature membrane proteins and/or modify their lipid-protein interactions as a means of inducing drug uptake (37). Mixed micelles appear to produce only limited disordering of surface mucosal cells, possibly by reducing the damaging effect of surfactants and somehow augmenting their enhancing activity. Absorption enhancements by surfactants, fatty acids, and mixed micelles may be attributable to improved solubility and/or stability of the drug being transported.

Stable molecules such as dextran and polyethylene glycol have been used in studies to address the size of the transport window that can be opened in the colon. Muranishi and Takada (44) have demonstrated that, on transport enhancement, low-molecular-weight drugs are directed twice as often to a transcellular route than the paracellular route, whereas molecules of approximately 20 kDa are directed almost equally through transcellular and paracellular routes. Enhanced transport with caprate, laurate, and mixed micelles suggest the opening of colonic pores of 14–16 Å, whereas enhancement with taurocholate or caprylate suggests the formation of 11–12 Å pores (37).

Chemical enhancers have been demonstrated to produce transport windows in colonic epithelia large enough for the passage of many bacterial toxins. Patients suffering from inflammatory bowel diseases and colitis typically have increased colonic permeability (45) attributable to bacterial toxins, both enterotoxins and cytotoxins that increase capillary permeability. Increased colon permeability associated with a diseased state may be useful in the treatment, in which improvement of the condition might reduce mucosal permeability and naturally reduce drug transport.

STRATEGIES FOR COLON-SPECIFIC DRUG DELIVERY

Attempts have been made to achieve colon-specific delivery of drugs. These include: 1) prodrugs and 2) polymers (enteric coated, those that are sensitive to degradation by bacterial enzymes, and matrices and hydrogels susceptible to degradation by bacterial enzymes).

Prodrugs

The prodrug sulfasalazine (SAS), used in the treatment of Crohn's disease, ulcerative colitis, and rheumatoid arthritis, is the earliest example of targeted drug delivery in the colon (Figs 2 and 3) (1). Only 12% of the drug is absorbed in the small intestine after oral delivery. When SAS reaches the colon after oral administration, the diazoreductase of the colon bacteria cleaves the azo bond, releasing 5-aminosalicylic acid and sulfapyridine into the colonic lumen (46). Osalazine (dipentum), which consists of two molecules of 5-aminosalicylic acid linked by an azo bond (47), was developed to directly deliver 5-aminosalicylic acid to the colon. Balsalazide is another prodrug that is reputed to benefit from a less toxic carrier molecule than that in SAS. Balsalazide is 5-aminosalicylic acid linked by a diazo moiety to 4-aminobenzoyl-β-alanine (48).

A comparable total release of 5-aminosalicylic acid in rats has been observed from SAS and 5-aminosalicylic acid azo linked to a polymeric prodrug consisting of polysulfonamidoethylene as the carrier molecule (polyasa) (49). Yet, the latter was more effective in reducing inflammation in the guinea pig ulcerative colitis model.

Fig. 2 Chemical structures of sulfasalazine (I), osalazine (II) and 5-ASA. (Adapted from Ref. 1.)

Fig. 3 Polymeric prodrug of 5-ASA. (Adapted from Ref. 1.)

The release of 5-aminosalicylic acid from polymeric prodrugs was dependent on the structure of the polymeric backbone (50). The drawback of coupling 5-aminosalicylic acid to polymeric backbone is the large amount of the drug that has to be taken orally.

A second approach that has been attempted involves prominent bacterial enzymes such as glycosidases and polysaccharides (51). Prodrugs were developed by coupling glucose or galactose to steroids such as dexamethasone, prednisolone, hydrocortisone, and fludrocortisone via a β -glycosidic bond. When these polar prodrugs are taken orally, they undergo minimal absorption in the small intestine. In the colon, the bacterial glycosidases cleave the polar moiety and release the steroid. Corticosteroids have been delivered in this manner to treat disorders of the large intestine. The side effects of corticosteroids can be minimized with this approach because of the minimal absorption of the drug in the small intestine as well as by dose reduction. The oral delivery of the prodrug form of dexamethasone produced the same therapeutic effect as

the parent drug in guinea pig models. However, the dose was lower with the prodrug (52). This approach has been extended to the development of glycoside prodrugs of budesonide and menthol and with dexamethasone poly (L-aspartate) (53).

The prodrug approach has been used where naproxen was conjugated to dextran by an ester linkage (54). The release of naproxen was 17 times higher in the cecum and in the colon homogenates of the pig than in control medium or homogenates of the small intestine. The dextran prodrugs of methylprednisolone and dexamethasone have also been developed (55). In both cases, most of the drugs were released in the contents of the large intestine, whereas only minor chemical hydrolysis occurred in the upper gastrointestinal tract.

Recent developments involve use of cyclodextrins that are absorbed only in minor quantities in the small intestine but are fermented by the colonic bacteria. In recent studies (56, 57), the use of biphenyl acetic acid conjugates of β -cyclodextrins was described. The ester conjugate released the drug preferentially when incubated with rat cecal contents, and almost no release was observed on incubation with the contents of the stomach or the small intestine.

Therefore, it can be seen that prodrug-based approaches are being used extensively to deliver drugs in increased amounts to the colon. Consistency of conversion from the prodrug to the active ingredients in vivo is a concern for these approaches because colonic bacterial populations can be modulated by diet, health, and a variety of antibiotics (29).

Polymers

Enteric coated

Drugs can be delivered locally and selectively to the colon by taking advantage of the difference in the pH of the different regions of the gastrointestinal tract. The pH in the gastrointestinal tract is low in the stomach but increases in the small intestine and the large intestine. For the purpose of targeting drugs to the colon, an outer enteric coating (for example, of cellulose acetate phthalate) can be used to protect the drug in the low pH of the stomach. In the small intestine (pH, 7.5), the enteric coating dissolves, exposing a polymeric coating, typically of ethylcellulose with microcrystalline cellulose and plasticizers. The polymeric coating is designed to stay intact in the small intestine until the dosage form reaches the colon. In the colon, bacteria are expected to digest the microcrystalline cellulose to allow for the disintegration of the polymeric coating around the drug. Such a scenario has been confirmed in a

study by Hirayama et al. (56), in which all the compressed tablets with dual coating remained intact in the small intestine and 85% of which disintegrated in the colon.

The problem with this approach is that the intestinal pH may not be stable because it is affected by diet, disease and presence of fatty acids, carbon dioxide, and other fermentation products. Moreover, there is considerable difference in inter- and intraindividual gastrointestinal tract pH, and this causes a major problem in reproducible drug delivery to the large intestine (58).

Spherical pellets containing 5% triamcinolone acetonide were prepared by Villar-Lopez and coworkers (59) by extrusion/spheronization after formulation with microcrystalline cellulose and/or a hydrophilic excipient such as lactose, sodium carboxymethylcellulose, or β -cyclodextrin. Their suitability for coating, with a view toward colonic drug delivery, was assessed in terms of their size, sphericity, and dissolution test response. The best results were afforded by a 5:90:5 composition of microcrystalline cellulose, β -cyclodextrin, and triamcinolone acetonide, prepared by complexation of triamcinolone acetonide with β -cyclodextrin before the addition of microcrystalline cellulose.

Formulations of 5-aminosalicylic acid that are commercially available use enteric coatings of pH-sensitive methacrylic resins called Eudragit[®] (Fig. 3). Both water-soluble and water-insoluble forms of Eudragit have been tested for colon targeting. Eudragit-L dissolves at a pH level above 5.6 and is used for enteric coating, whereas Eudragit-S, which dissolves at a pH level above 7.0 (attributable to the presence of higher amounts of esterified groups in relation to carboxylic groups) is used for colon targeting. Studies have revealed that Eudragit-S exhibits poor site specificity (60).

In a study performed by Khan et al. (61), lactose placebo tablets were coated using different combinations of Eudragit L and Eudragit S. The Eudragit L–Eudragit S combinations (w/w) studied were 1:0, 4:1, 3:2, 1:1, 2:3, 1:4, 1:5, and 0:1. The disintegration data obtained from the placebo tablets demonstrate that disintegration rate of the tablets is dependent on 1) the polymer combination used to coat the tablets, 2) the pH of the disintegration media, and 3) the coating level of the tablets.

It has been shown that polymers with nonesterified phthalic acid groups dissolve much faster and at a lower pH than those with acrylic or methacrylic groups. The presence of plasticizer and the nature of the salts in the dissolution medium influence the dissolution rate (62).

In a recent study by Peeters and Kinget (63), the free carboxylic groups of Eudragit-S were partially methylated. The product was found to dissolve in water at a slightly higher pH compared with the original polymer. The

effectiveness of this product as a colon-specific coating material had been established with human volunteers using in vivo scintigraphic studies (64).

In a study by Gazzaniga and coworkers (65), an oral dosage form was developed, consisting of a core with two polymeric layers. The outer layer, which was an enteric coating, dissolved at a pH level above 5. The inner layer, made up of hydroxypropylmethylcellulose, acted as a retarding agent to delay drug release for a predetermined period. The thickness of the inner layer determined the lag time. This system was found to release drug in the colon of the rat between the 5th and 10th h.

A pulsed system, called the Time-Clock System, has been developed. The system comprises a solid dosage form coated with a hydrophobic surfactant layer to which a water-soluble polymer is attached to improve adhesion to the core (66). The thickness of the outer layer determines the time required to disperse in an aqueous environment. After the dispersion of the outer layer, the core becomes available for dispersion. An advantage is that common pharmaceutical excipients can be used to manufacture the system. Studies performed in human volunteers showed that the lag time was not affected by gastric residence time. Also, the dispersion of the hydrophobic film was not influenced either by the presence of intestinal digestive enzymes or by the mechanical action of the stomach.

Another system based on the same principle as the Time-Clock System, called the Time-Controlled-Explosion Drug-Delivery System, has also been developed (67). It contains a four-layered spherical structure, with a core containing the drug, a swelling agent, and a water-insoluble polymer membrane made of ethylcellulose. This system is characterized by rapid drug release with a programmed lag time. On contact with water through the polymeric membrane, the swelling agent expands and finally explodes, leading to release of the contained drug. Drug release is not affected by pH, but the lag time is a function of the thickness of the outer polymeric membrane. A similar approach based on ethylene–vinyl acetate polymers was tested for release of the drug isosorbide-5-nitrate (68).

Ishibashi and coworkers have recently developed a Colon-Targeted Delivery Capsule based on pH sensitivity and time-release principles (Fig. 4) (69). The system contains an organic acid that is filled in a hard gelatin capsule as a pH-adjusting agent together with the drug substance. This capsule is then coated with a three-layered film consisting of an acid-soluble layer, a hydrophilic layer, and an enteric layer. After ingestion of the capsule, these layers prevent drug release until the environmental pH inside the capsule decreases by dissolution of the organic acid, upon which the enclosed drug is quickly released.

Fig. 4 Design of the colon-targeted delivery capsule: a) gelatin capsule; b) active ingredient; c) organic acid; d) enteric layer; e) hydrophilic layer; and f) acid-soluble layer. (Adapted from Ref. 106.)

Therefore, the onset time of drug release is controlled by the thickness of the acid-soluble layer. In fact, capsule disintegration (and, thus, drug release) does not start until 5 h after gastric emptying regardless of whether the formulation is administered to fasted or fed subjects.

Recently, Yoshikawa et al. (70) reported a new *in vitro* dissolution test called the rotating beads method for drugs formulated in pressure-controlled colon-delivery capsules. This dissolution method was applied to acetaminophen sustained-release tablets and two other drugs having low solubility in the colon, tegafur and 5-ASA. There was good correlation between the *in vitro* dissolution rates and the *in vivo* absorption rates.

In the development of the aforementioned time-dependent systems, care has to be taken to ensure a homogenous coating. If the coat is inhomogenous, there will be a modification of the coating rigidity, possibly leading to undesirable infiltration of the aqueous medium and, in turn, undesired alteration of the lag time before which the drug is supposed to be released.

Polymers sensitive to degradation by bacterial enzymes

Drugs can be administered locally and selectively to the colon if they are enclosed in a dosage form such as a capsule coated with an azo-aromatic cross-linked polymer subject to cleavage by azo-reductases of the colonic microflora. This approach of coating a drug with biodegradable material for colon targeting can be used to administer a large amount of the drug. Moreover, the rate of drug release is dependent on the activity of the bacterial enzymes in the colon rather than on that of the host.

A system was developed by Saffran and coworkers (68) in which insulin or vasopressin was encapsulated in a

gelatin capsule coated with an impermeable polymer. The coat, prepared by using azo functional cross-linking agents based on divinylazobenzene, was resistant to degradation in the stomach and the small intestine. However, problems were encountered attributable to variability in absorption, which may be because of intra- and intersubject differences in microbial degradation of the coating that may not be hydrophilic enough. Indeed, Kimura et al. (72) noted that only polymers with a sufficient degree of hydrophilicity could be degraded within an acceptable period of time. However, there is a possibility of premature drug release if the polymeric coating is too hydrophilic. The impact of the spacer length of the incorporated azo agent appears to be of limited importance.

A popular theory with azo materials is that their degradation products are always aromatic amines such as azo dyes. Ueda and coworkers observed that the azo bonds in segmented polyurethanes were reduced to hydrazo intermediates after incubation with human feces because no decrease in the molecular weight was observed (73). It was then theorized that drug release from pellets coated with these azo polymers was attributable to both a conformational change and a breakdown of the film structure. Other studies also concluded that the polymers were reduced to hydrazo intermediates or were completely degraded to aromatic amines depending on their hydrophilic/hydrophobic nature.

There has been no definitive conclusion regarding the toxicity of azo polymers, although it is known that azo dyes contain several potential carcinogens. To avoid possible azo-related toxicity issues, other biodegradable natural substances capable of forming coatings that degrade in the colon have been studied. Common problems encountered with these natural biodegradable materials are poor film-forming capability and excessive water solubility. Therefore, efforts are currently being made to mix these natural materials with other synthetic polymers to obtain a film-forming mixture or to derivatize them to decrease their water solubility.

Natural polysaccharides such as pectin, xylan, and guar gum are not digested in the human stomach or small intestine, but are degraded in the colon by the resident bacteria. Recent studies conducted with 5-ASA (74) and indomethacin (75) confirmed that selective delivery of these drugs to the colon can be achieved using guar gum as a carrier because guar gum protects the drugs from being released in the physiological environment of the stomach and the small intestine. The polysaccharides under active investigation for colon-specific drug delivery include pectin and its salts, chondroitin sulfate, amylose, and inulin.

Fig. 5 Chemical structures of Eudragit. (Adapted from Ref. 69.)

Veervort and Kinget (76) demonstrated that the incorporation of inulin in Eudragit films resulted in increased permeability with increase in incubation time in the degradation medium (Fig. 5) (1). After 8, 16, and 24 h of incubation, the permeability coefficient increased with a factor 6, 20, and 70, respectively. However, because of manufacturing problems resulting from the high methoxy pectin content, film coatings were developed consisting of ethylcellulose and pectin. Wakerly and coworkers manufactured (77) film coatings with ethylcellulose and pectin. In vitro degradation studies indicated that release was controlled by the ratio of ethylcellulose and pectin.

Lorenzo-Lamosa and coworkers manufactured a system in which chitosan microcores were entrapped within acrylic microspheres of Eudragit L-100 and Eudragit S-100, forming a multireservoir system (78). This system was designed to combine the specific biodegradability enforced by colonic bacteria with pH-dependent release of the drug sodium diclofenac and tested in in vitro systems. A continuous release for 8–12 h was obtained at the pH in which the Eudragit coats were

soluble. The researchers have proposed a combined mechanism of release, comprising dissolution of the Eudragit coating, swelling of the chitosan microspheres, dissolution of the drug, and its further diffusion through the chitosan gel cores (Fig. 6) (78).

Recent studies conducted by Tozaki et al. (79) with 5-ASA-containing chitosan capsules revealed that the drug concentration in the colon was higher than that afforded by a suspension of the drug. Ramdas et al. (80) used the bioadhesiveness of polyacrylic acid, alginate, and chitosan in formulations with drugs such as 5-fluorouracil and insulin to bypass the acidity of the stomach and to release loaded drug for long periods into the intestine (80). Chitosan succinate and chitosan phthalate have been used successfully as potential matrices for the colon-specific oral delivery of sodium diclofenac as demonstrated by Aiedeh and Taha (81).

Another natural polysaccharide, amylose, when prepared under appropriate conditions, is not only able to produce films, but is also found to be resistant to the action of pancreatic α -amylase while remaining vulnerable to the colonic flora (82). However, incorporation of ethylcellulose was necessary to prevent premature drug release through simple diffusion (83). In vitro release of 5-aminosalicylic acid from pellets coated with a mixture of amylose–ethylcellulose in a ratio of 1:4 was complete after 4 h in a colonic fermenter. By contrast, it took more than 24 h to release only 20% of the drug under conditions that mimic that of the stomach and the small intestine.

A suspension of natural polygalactomannans in polymethacrylate solution applied to a degradable coating around the drug core delayed the drug release in the small intestine but was degraded by bacterial enzymes in the colon (83). This formed the basis for studying the usefulness of guar gum containing polygalactomannans as a carrier for colonic drug delivery. Matrix tablets of dexamethasone were evaluated for colon-specific drug;

Fig. 6 Scheme of possible drug release from the Eudragit microencapsulated chitosan microspheres. (Adapted from Ref. 83.)

delivery with preparations containing guar gum (84). In a γ -scintigraphic study, guar gum in the form of matrix tablets was evaluated for its performance in healthy human volunteers using technetium-99m-DTPA as tracer (85). It was observed that the matrix tablets entered the colon intact and released the bulk of the tracer in the colon by virtue of the enzymatic action of the colonic bacteria.

Studies conducted by Bauer and Kusselhut have demonstrated that lauryl dextran esters can be film-forming and have been found to release tablets containing theophylline selectively in the colon (86). Theophylline tablets were coated with a dispersion of 4% lauroyl dextran in a study performed by Hirsch and coworkers (87). Theophylline dissolution was monitored for 4 h in a buffer of pH 5.5, after which the passage to the cecum was simulated by the addition of dextranase. Almost linear dissolution was observed during the first 4 h. The rate of release was inversely proportional to the amount of ester applied on the coating. After the addition of dextranase, the coatings were degraded, leading to the complete release of the drug in less than 2 h, after the addition of the enzyme. The results of these studies in which natural biodegradable polymers have been derivatized using acceptable reactants are promising as far as colon-specific drug delivery is concerned.

Matrix and hydrogels susceptible to degradation by bacterial enzymes

In this design, the active ingredient, the degradable polymer, and other additives are compressed to form a monolithic or multiparticulate solid dosage form. The drug is embedded in the matrix core of the degradable polymer. Biodegradable matrix systems of cross-linked chondroitin sulfate with different levels of cross-linking have been tried for the delivery of indomethacin. A direct relationship was found between the degree of cross-linking of the polymer and the amount of drug released in the rat cecal content (88).

Rubinstein and Rudai (89) observed that highly compressed matrices based on pectin in the form of plain tablets or compression-coated tablets were able to retain indomethacin in simulated gastric and intestinal juice before becoming degraded in a medium that contained enzymes for degrading pectin. In vitro experiments showed that methoxyl pectin, when added as a compression coat, was capable of protecting a core tablet under conditions mimicking mouth-to-colon transit and was susceptible to enzymatic attack in the colon. A greater degree of methoxylation of pectin resulted in lower susceptibility degradation to by colonic bacterial enzymes, whereas the presence of calcium increased the vulnerability to enzymatic attack (90).

The problem with the aforementioned monolithic unit system is that it tends to be detained at the ileocecal junction, leading to drug loss before entry in the colon. To circumvent this problem, multiparticulate dosage forms were devised that passed freely through the ileocecal junction. In a recent study, a multiparticulate system, which was based on amidated pectin, was tested (91). Coating of the amidated pectin beads with chitosan significantly reduced the release of sulfamethoxazole and indomethacin in simulated gastric and intestinal juice compared with noncoated beads.

Macleod et al. (92) have studied the potential of pectin: chitosan: hydroxypropylmethylcellulose films for colonic drug delivery (92). The results showed that in all cases, the tablets were able to pass through the stomach and small intestine intact. The tablets started to break up once they were in the colon, as a result of degradation of the coating by colonic bacteria.

Kopecek and coworkers (Fig. 7) (93) have developed novel types of hydrogel capsules, based on acrylic acid, *N,N*-dimethylacrylamide and *N*-tert-butylacrylamide cross-linked with 4,4'-di(methacryloylamino)azobenzene (94). These hydrogels did not swell significantly in the stomach. However, in transit through the small intestine, swelling increased because of increased pH. In the colon, the degree of swelling reached a threshold when the cross-links became accessible to bacterial azoreductases, which in turn, caused the breakdown of the hydrogel and release of the drug. The rate of degradation was found to be directly related to the equilibrium degree of swelling of the hydrogels and inversely proportional to the cross-linking density. Hydrogels prepared by cross-linking polymerization but having the same polymer composition and cross-link structure predominantly followed a bulk degradation-like process. In contrast, hydrogels prepared by cross-linking polymeric precursors or by a polymer-polymer reaction predominantly followed a surface erosion process at a low degree of cross-linking and a bulk degradation-like process when the degree of cross-linking increased (95). In a comparative study to determine the degradation rate of the azo functionality present in a soluble azo polymer and a hydrogel, it was observed that the degradation rate was 125 times lower than that of the soluble azo dye.

Hydrogels of dextran that used diisocyanate as the cross-linking agent were found to be capable of releasing a drug only in the distal part of the colon, where the conditions for absorption are not as conducive as the proximal part (96). pH-sensitive dextran hydrogels were prepared by activation of dextran (T-70) with 4-nitrophenyl chloroformate, followed by conjugation of the activated dextran with 4-aminobutyric acid and

Fig. 7 Schematic representation of the synthesis of hydrogels by cross-linking of polymeric precursors. (Adapted from Ref. 93.)

cross-linking with 1,10-diaminodecane (97). The release rate of bovine serum albumin from this system was further enhanced by the addition of dextranase in buffer solutions. However, in a study in which Hirsh et al. (98) investigated lauroyldextran and cross-linked galactomannan as micro-biologically degradable film-coating materials for site-specific drug delivery to the colon, the ideal zero-order dissolution before and quick degradation after enzyme addition was not realized. On the other hand, hydrogels made by copolymerization of 2-hydroxyethyl methacrylate with 4-methacryloyl-oxyazobenzene led to the release of aniline when the hydrogel was degraded by the colonic bacterial enzymes (99). Another study reported the biodegradable properties of guar gum, which was cross-linked with borax (100). This system was found to be capable of releasing drugs in the proximal part of the colon.

Hydrogels that are based on natural products are more acceptable from the standpoint of toxicity-related issues and are therefore preferable to azo-based polymers. However, chemical derivatization, if performed without

proper understanding, can lead to modifications of the hydrogels to products that will not degrade readily in the colon because it is possible that the new structures will not be recognized by the colonic bacterial enzymes for degradation. Also, bulk degradation is preferred to surface erosion because it leads to a more rapid rate of drug release. The one major drawback with the use of hydrogels and matrix systems is that only a limited amount of drug can be incorporated. Thus, when a large amount of drug is required at the target site in the colon, this may not be the most suitable carrier.

CONCLUSION

A great deal of research has been conducted in the past two decades in delivery systems for targeting drug release in the colon. This is clearly a region of the gastrointestinal tract worthy of attention because it does not have the

hostile environment that is responsible for drug degradation in the stomach and the small intestine. Local therapy of pathologies of the colon and reduced drug availability attributable to degradation of the active ingredients by digestive or mucosal enzymes can benefit from colonic delivery. However, the large intra- and intersubject variation in gastrointestinal pH makes the delivery systems based on pH-dependent polymers less suitable for targeted drug delivery to the colon. Therefore, systems that rely solely on the prevalent conditions of the colon (for example, those that depend on degradation by colonic bacteria for drug release) are promising. However, care should be taken in designing such systems because there are concerns regarding toxicity issues with the use of azo-based polymeric delivery systems. The natural polymers, on the other hand, may not have sufficient film-forming capacity and also may be less prone to degradation in the stomach after chemical derivatization. A major problem in comparing different delivery systems to the colon is that the degradation studies are carried out in different experimental conditions. Moreover, despite promising results in animal studies, none of the polymeric systems have yet been tested clinically. Clearly, much work remains to be done to satisfactorily answer the concerns that have surfaced about colon-specific drug delivery.

DRUG DELIVERY—OPHTHALMIC ROUTE

Massod Chowhan

Alan L. Weiner

Haresh Bhagat

Alcon Research Ltd., Fort Worth, Texas, U.S.A.

INTRODUCTION

Delivery of medication to the human eye is an integral part of medical treatment. The delivery of drug to the site of action has been practiced since ancient times, which successively advanced in a variety of ophthalmic dosage forms. The writings pertaining to eye medications have been found on Egyptian papyri. Between 20 BC and AD 50, Greeks and Romans practiced the delivery of the necessary components of eye medication by dissolving them in water, milk or egg white (1). They used the term *collyria* for such preparations. The term *belladonna* or “beautiful lady” evolved during the middle ages from such collyria, which contained components to dilate the pupils of a lady’s eyes for cosmetic purpose (2). The collyria gave rise to the birth of modern-day eye drop solutions.

Prior to World War II and well into the 1940s, most solutions for eye use were compounded by the pharmacist in the community pharmacy and were intended for immediate use, perhaps due to an unconfirmed stability of the drug (2). The availability of such solutions in a sterile dosage form marked the most important milestone in this century for the modern day eye drop solution. Alcon Pharmacy (currently known as Alcon Laboratories Inc.), a dispensing pharmacy during the day and a manufacturing pharmacy during the night, was the first provider of sterile ophthalmic solutions in 1947, long before the Food and Drug Administration (FDA) adopted a position in 1953 that a nonsterile ophthalmic solution was considered adulterated. Subsequently the United States Pharmacopoeia (USP) adopted sterility as requirement for ophthalmic solutions in 1955 (3).

The traditional era of the solution-only dosage form for use in the eye ended in the 1950s with the availability of suspension dosage forms. Solid drug particles of cortisone acetate were first suspended and a suspension product commercialized. In an unorthodox approach, for the first time clinical studies revealed that a sufficiently reduced particle sized drug could be instilled on ocular surfaces. This resulted in the availability of water insoluble or

sparingly soluble drugs for the mitigation of ophthalmic disorders in suspension dosage forms.

The successful experimentation of delivering sparingly soluble drugs in a suspended form led the way for products with added values beyond simple presentations. Increasing awareness of basic properties of drug molecules and the wide spread availability of excipients further advanced the discoveries of value added deliveries. Jani et al. (4) reported such delivery of β_1 -adrenergic antagonist as a bound drug to cationic polymer resin beads, suspended in an aqueous vehicle. The authors were able to reduce ocular discomfort of betaxolol yet maintain the therapeutic efficacy of the drug for controlling intra ocular pressure.

Gressel et al. (5) reported viscosity modifiers for enhancing intended effects on an ocular surface. A polyacrylic polymer was used to increase viscosity to a gel consistency and thereby enhancing the treatment of symptoms for dry eyes. Sullivan reported efficacy of carbomer gel in improving the number of subjective and objective symptoms of moderate-to-severe dry eye syndromes (6). Such a gel vehicle offered an advantage of reducing frequency of instillation and has resulted in a commercial product (Pilopine HS Gel).

Recognizing the value of rheological properties of polymers facilitated discovery of gel forming solutions for drugs such as timolol maleate. In these systems, timolol is formulated in an aqueous vehicle which on contact with the ocular surface changes to a gel like consistency, thereby, extending the duration of contact. Extending the contact time improved bioavailability thereby reducing the frequency of the dosage to once daily instillation. Two extended duration timolol maleate products, one containing gellan as a gel forming ingredient (Timoptic XE), and the other with xanthan (Timolol Gel Forming Solution) have been approved for commercial use. Shin reported a single daily application of such dosage in reducing intraocular pressure in human subjects (7). Beyond the use of solutions, suspensions and gels, further developments have been made in formulation of creams and ointments, intra-ocular injections, viscoelastic solutions and newer devices and inserts.

EVOLUTION OF OCULAR DRUG DELIVERY SYSTEMS

Topical ocular application of controlled drug delivery systems is a relatively new science compared to earlier ocular dosage form, with roots beginning in the late 1960s to early 1970s.

Delivery of Drugs from Contact Lens Materials

The earliest attempts to significantly prolong the action of drugs applied to the eye focused on using existing systems known in the ophthalmic field. In particular the most well known and characterized solid systems for ocular use are hydrophilic contact lenses. The primary material initially developed for constructing hydrophilic contact lenses was hydroxyethyl methacrylate (HEMA). Many variations of HEMA polymers have since been produced for contact lenses wherein the HEMA is typically copolymerized with methylmethacrylate, ethoxyethylmethacrylate, 1,3-propanediol trimethacrylate, ethylene dimethacrylate, allyl methacrylate, ethylene glycol dimethacrylate, dimethyl oxybutyl acrylamide, or vinyl pyrrolidone. Depending on copolymer composition and cross-linkage, hydrogels of this type range from 38 to 79% water content. Because of this property, it is possible to load polymers of this type with drug by soaking them in an aqueous solution containing the drug. This application was first reported in the early 1970s in papers examining uptake and release of agents such as fluorescein from Bionite lenses produced by Griffin Laboratories and Soflens lenses from Bausch and Lomb. Studies showed significant differences in uptake and release rates for the two types of lenses. Today these results are not unexpected as it has been shown by Sorenson et al. (8) that elimination of radiotracers from presoaked contact lenses are cleared more slowly in lenses containing higher water content and thicker dimensions. In low water content lenses (minimum of 38%), elimination constants of a technetium label were in the range of $0.278\text{--}0.155\text{ min}^{-1}$. In contrast the elimination constant of a 75% hydrated lens was 0.029 min^{-1} , a factor of 7–10 times slower. These differences have been confirmed in other studies using specific drugs such as tobramycin (9).

From an efficacy point of view, early studies with HEMA based lenses were conducted using pilocarpine, the key available glaucoma drug during that era. Several studies reported improvements in reduction of intraocular pressure and corneal drug flux using presoaked lenses containing lower pilocarpine concentrations than standard

drops (10–14). In later studies following the identification of timolol as a glaucoma agent (15) it was found that polyvinylmethacrylate circular disks of 13-mm diameter and 0.5-mm thickness will release timolol differentially depending on the addition of a basic additive (disodium phosphate). An enhancement in the rate of release and a shifting of peak timolol levels from 4 h to 30 min were observed when formulated with the additive.

Antibiotics have also been examined for uptake and release from contact lens materials. Impregnation of various hydrogels constructed of various methacrylate and polyvinylpyrrolidone copolymers with erythromycin and erythromycin estolate were effective in slow releasing drug over a period sufficient to suppress *Chlamydia* infection in a monkey model (16, 17). As well, modest increases in intraocular gentamicin have been observed upon administration of gentamicin soaked hydrogel lenses in rabbits (18). Clinically, drug penetration of gentamicin, chloramphenicol, or carbenicillin from hydrogel lenses was found to be higher than subconjunctival injection of control solutions over a 2–12-h period posttreatment (19). In prepolymerized poly HEMA minidisks loaded with particles of sulfisoxazole, extended release over a 168-h period was achieved (20). This proved to be successful in treating a *Staphylococcus aureus* infection model in rabbits from one time administration of the minidisk as compared to 3 times daily control solutions.

Absorption and washout characteristics of drugs from poly HEMA based lenses are drug dependent. For example, following a 7-day immersion, increasing levels of uptake are observed for norepinephrine, gentamicin, pilocarpine and dexamethasone, respectively (21). Washout of these drugs from the lens was nearly complete (83–98%). Maximum amounts of these drugs taken up into these lenses represented only one tenth of the dose achievable by application of topical drops. Total uptake of these agents into polymethylmethacrylate was also quite low. These results were supported by earlier studies indicating that intraocular poly HEMA does not act as a significant sponge or long term reservoir for drugs such as dexamethasone, chloramphenicol, epinephrine and pilocarpine (22).

While the majority of reports have examined topical release of drugs from contact lens materials, the implantation of these materials, as is common for intraocular lenses, has been reported. One such example was recorded by Shing et al. (23) who implanted poly HEMA pellets loaded with fibroblast growth factor (FGF)-sucralfate into the cornea as a means to develop a corneal neovascularization model for testing of anti-angiogenic agents. Neovascularization was produced beginning at day 2 and reaching a maximum at day 11 with an elongation rate of 0.41 mm/day until day 13.

Ocusert

At about the same time as investigations were being carried out with contact lens materials for drug release, an ethylene vinyl acetate (EVA) membrane device, Ocusert[®] was developed by the Alza Corp. (Palo Alto, CA) and eventually commercialized in 1974 (20, 24–28). Ocusert is an elliptical shaped device consisting of two outer layers of rate controlling EVA, and an inner layer of pilocarpine in an alginate gel. The device is designed for continuous release of the drug at a 20 or 40 $\mu\text{g/h}$ rate over 7 days. Enhanced release of the pilocarpine in the higher rate device is facilitated by addition of a flux enhancer, di-(ethylhexyl)phthalate. While this device functions effectively in a specific niche of difficult to manage glaucoma patients, it has not been universally adopted for use because of unsatisfactory control of IOP in some patients, ejection of the device from the eye, and irritation or tolerance difficulties (29–31).

Erodible Polymeric Delivery Systems

During the same period that reports appeared on the Ocusert device, research was progressing on the use of erodible polymer systems for ophthalmic drug delivery. This research blossomed in the early 1980s with a particular focus on polymers employed in the manufacture of absorbable sutures. Release of many ophthalmic drugs from polymeric matrices either via dissolution or erosion was investigated. In addition to the development of slower releasing carrier systems, many papers have since appeared on the use of viscosity additives and bioadhesives to extend retention of delivery systems in the eye. For example albumin nanoparticles containing pilocarpine are better retained by the inclusion of methylcellulose, hydroxypropylmethylcellulose, polyvinylalcohol, sodium carboxymethylcellulose, carbopol 941, hyaluronate or mucin in the formulation (32). Similar effects are noted when carbopol is used in coating ophthalmic gentamicin drug delivery inserts comprised of hydroxypropylcellulose, ethylcellulose, and polyacrylate (33).

Polyvinylalcohol

Polyvinylalcohol disks for delivery of drugs to the eye were proposed as early as 1966 for potential use by astronauts (34). Pilocarpine loaded disks exhibited sustained miosis and IOP reduction in human subjects. Maichuk (35–37) has elaborated on these early studies by showing that PVA films containing pilocarpine, antibiotics, or antimetabolites increased drug concentration in the tear film and prolonged the delivery times. Similarly, bioavailability, miotic activity in rabbits, and intraocular

pressure control in human glaucoma subjects were all enhanced over a 24-h period with PVA/pilocarpine–PAA disks of 4-mm diameter and 0.4-mm thickness prepared from cast films (38). A PVA film device termed NODS (“new ophthalmic delivery system”) has also been utilized for studying improvement in delivery of pilocarpine, tropicamide, chloramphenicol, and proparacaine (39). Heat-treated PVA membrane sandwiches have been prepared with 5 mg of ganciclovir, which released at a rate of 0.25 $\mu\text{g/h/mm}^2$ over a 1-week period (40). Similarly, pellets of either thalidomide (41), cyclosporin (42), or leflunomide (43) with either PVA incorporated into the pellet or coating the pellet have exhibited sustained release of those drugs either in vitro or in the vitreous or subconjunctival spaces.

Delivery of drugs from collagen shields

The concept of drug delivery from contact lenses was extended to include contact lens-shaped collagen shields after their approval for use directly on the surface of the eye to treat corneal wounds (44–46). Several types of collagen shields are commercially available under such names of ProShield (Alcon Laboratories, Inc., Fort Worth, TX), Bio-Cor (Bausch & Lomb, Clearwater, FL), and Soft Shield (Oasis, Glendora, CA). The collagen for these products is derived from a bovine or porcine source with dimensions of 14.5 mm in diameter and thickness between 0.012 and 0.071 mm. In the eye these shields dissolve over a 12–72 h period depending on the amount of cross-linkage. Similar to the earlier contact lens studies, the majority of investigations examining release of active agents from collagen matrices first involve loading of active agent into the shield by soaking in the agent over a sufficient period of time (47). Because of the relatively large pore size, diffusion into and out of the shield does not typically surpass 2–3 h.

Many studies have looked into prolongation of aminoglycoside antibiotic release from collagen matrices. Tear film and topical tissue levels (sclera and cornea) of gentamicin delivered from collagen matrices is elevated over controls as determined by pharmacokinetic evaluation of ¹⁴C-gentamicin (48). In models of *Pseudomonas keratitis* in rabbits (49, 50), collagen shields loaded with gentamicin (49, 50) or tobramycin (51) have produced significant reductions in colony-forming units (CFU) over control animals given drug alone. However, changing from the shield design to either a doughnut (52) or disk (53) does not seem to offer an improvement in gentamicin release. Although aqueous humor levels of gentamicin are not achieved when using shields presoaked in 40 mg/ml gentamicin as compared to drops (54), levels of tobramycin delivered from shields

have been detected in aqueous humor (55, 56). Neither repetitive drop treatment nor release from collagen shields results in the establishment of vitreous drug levels. More extensive studies have been reported on collagen shields to deliver tobramycin (57–62) in various other tests of ocular trauma. Enhanced delivery of procaine penicillin, erythromycin, erythromycin estolate (63), silver nitrate 1%, povidone-iodine 5%, chlorhexidine gluconate 1% (64), and amphotericin 5% (65) from collagen shields also has been reported.

Similar to antibiotic studies, delivery of corticosteroids from collagen shields has been demonstrated to produce prolongation of effects, enhanced penetration, and increased efficacy (66–69).

Antimetabolites such as 5-fluorouracil (5-FU) have been used experimentally for retarding the healing of incisions made to improve outflow of aqueous humor and reduction in intraocular pressure in glaucoma patients. Several groups have examined the potential of 5-FU loaded collagen shields for improving current therapy over 5-FU alone (10, 71–73). Increases in duration of action and success rates have been noted. Another antimetabolite, trifluorothymidine, when released from collagen shields was investigated as a potential treatment for ulcerative herpetic keratitis (74). In these studies, cornea and aqueous humor levels were 19–42% higher when eyes were treated with drug loaded shields.

More effective treatment of glaucoma has also been attempted using collagen shield technology. In this regard, shields have been shown to prolong delivery of pilocarpine (75–77) and metipranolol (78).

Collagen disks have had their greatest application in the treatment of wounds. Enhancement of the inherent protective property of the material has been investigated with the subsequent inclusion of growth factors. Collagen disks soaked for 5 min in platelet derived or epidermal growth factors (100 µg/ml) was capable of increasing the wound healing rates of debrided corneas in rabbits (79). Following placement on the cornea, collagen shields containing tissue plasminogen activator shortened fibrin clot lysis time by 50% over controls (80). Another wound modulator, cyclosporin A delivered by topical collagen shields, has been reported to be 10-fold higher in cornea and aqueous humor over an 8-h period as compared to controls (81).

Poly(lactide) (PLA), polyglycolide (PGA) and polycaprolactone (PCL)

A further extension of drug delivery using naturally biodegrading materials other than collagen included the application of known eroding suture materials. Polylactic acid, polyglycolic acid and polycaprolactone are the

primary materials used in dissolvable sutures including Dexon® (Davis and Geck, Danbury, CT) and Vicryl® Polyglactin (Ethicon, Somerville, NJ). The key focus of ocular drug delivery from these polymers has been for sustained release of 5-FU. Sustained release 5-FU from PLA/PGA copolymer microspheres had been utilized for applications in glaucoma filtration surgery and proliferative vitreoretinopathy (82–86). Release of 5-FU is controllable over a 7-day period in vitro and when injected into the vitreous PLA microspheres (with 2 mg drug) degrades over a 48-day period. In a PVR model, tractional retinal detachments are reduced from 60 to 10% of animals when 1.25 mg of drug is delivered from PLA microspheres as compared to control injections (83). In animals, vitreous concentrations of 5-FU delivered from PLA/PGA microspheres (250 µg) or rods (1 mg) can be detected from periods between 11 days (87) and 21 days (88–90). PLA/PGA devices incorporating 5-FU prevented retinal detachments in an experimental model that was not responsive to drug alone. PLA/PGA disks containing 5-FU are also efficacious for periods greater than one month in applications for glaucoma filtration surgery (91, 92). Devices of this type have shown some inflammatory and vascularization reactions depending on site of implantation (90, 93). PLA microspheres have shown sustained efficacy in delivering other antimetabolites such as doxorubicin (94, 95).

PLA, PGA and PCL delivery systems have also proven to be of value in delivering glaucoma agents. Nanoparticles (150-nm diameter) and nanocapsules (300-nm diameter) constructed from polycaprolactone incorporating either 1% carteolol chlorhydrate or 0.5% betaxolol were shown to be more effective than controls in hypertension models (96, 97). Prolongation of miosis has also been observed in rabbits receiving microcapsules constructed from PLA and containing pilocarpine hydrochloride (98).

Anti-inflammatory and anti-infective agents such as indomethacin, fluconazole, and dexamethasone have been incorporated into PLA, PLG, or PCL carriers (99–101). Significant increases in either drug concentration or duration of action were noted.

Polyanhydrides, polyorthoesters, and polyalkylcyanoacrylates

Beyond the use of suture materials, newer erodible polymeric materials were introduced in the 1980s as potential ophthalmic carrier systems for release of drugs.

As with PLA or PLG carriers, the application of either polyanhydride or polyorthoester polymers for 5-FU sustained release in glaucoma treatment or PVR has been investigated (102–107). Using compression

techniques, polyanhydride devices constructed from combinations of (*p*-carboxyphenoxy)alkanes with sebacic acid have been produced. Disk or T-shaped polyanhydride devices containing between 10 and 20% 5-FU prolonged IOP reduction and bleb survival in filtration models or better inhibited tractional retinal detachments in PVR models than standard drug controls. Similar effects on extended filtration bleb survival and IOP reduction have been observed for polyanhydride implants containing daunorubicin (108) or mitomycin C (109). Release of drugs from polyanhydride implants have been examined when administered subconjunctivally (etoposide) (110) or in the vitreous or anterior chamber (gentamicin) (111). In these reports slow release rates were established at least over a 1-week period. In context of vitreous delivery, polyorthoesters have been shown to release ganciclovir for 144 h which is controllable by the pH of the dissolution media (112).

Ocular distribution and elimination of biodegradable polyalkylcyanoacrylate nanoparticles has been examined in a number of reports (113–117). Pilocarpine containing polybutylcyanoacrylate nanoparticles alone or in gel type formulations are capable of enhancing and prolonging the miosis and pressure lowering response in various animal models (118–122).

Non-erodible Systems

Distinct from the development of contact lens materials or the Ocusert in the 1970s, additional promising delivery systems and materials have emerged with the more recent focus on development of intraocular applications for treatment of macular degeneration, cataract, retinopathy, and inflammation.

Vitrasert®

The Vitrasert, approved in 1996 and currently marketed by Bausch and Lomb is an ethylene vinyl acetate cup encasing a cylindrical core of ganciclovir, which is covered on one or two surfaces with a permeable PVA membrane to allow for diffusion (123–134). At the base of the cup is an anchoring strut made of PVA to allow for suturing. The drug core diameter of the device is 2.5 mm. Sustained levels of the drug are maintained in the vitreous over a period of 6–8 months in the treatment for cytomegalovirus (CMV) induced retinitis. This device has also been investigated for the delivery of 5-FU (126–130), flurbiprofen (131) cyclosporin (132), dorzolamide (133), and dexamethasone (134) when implanted at various sites. A variation on this device has been constructed using a core of ganciclovir/poly(lactide-glycolide) encased in a

crosslinked poly[HEMA-co(PVA-AA)] film that releases the drug in the vitreous over 63 days (135).

Silicones

Ophthalmic practice has long employed silicone polymers in surgeries utilizing scleral buckles and sponges, retinal tamponade and foldable intraocular lenses. Silicone elastomers and rubbers are hydrophobic in nature and therefore support long term payout characteristics for many drugs. Silicone polymer disks of 4–5-mm diameter termed minidisks have been studied for the release of gentamicin when placed in the conjunctival cul-de-sac (20, 136). Slow release of the drug is observed over a period of 10–14 days with tear concentrations in the range of 2.5 ppm during this period. Nanoparticles of silicone in the 150–200 μm size range can be made and when containing timolol effectively prolonged release of the drug (137). Sealed silicone tubes 1.46 mm ID by 15 mm length and filled with 2.5–20 mg/ml solutions of timolol slow release the drug over 8 h in vitro (138) or in vivo (139). Recently, development of a solid noodle-like silicone controlled drug delivery rod for the deep cul-de-sac (fornix) known as the Ocufit SR® has been reported (140–143). These rods have been shown to slow release oxytetracycline or diclofenac over several weeks and have shown good wear compliance in humans (144, 145). Liquid silicone can also be used as a surface coat in developing delivery devices. This approach has been reported for polydimethylsiloxane coated solid drug implants that are used to enhance sustained delivery in the eye (41, 42).

CONCLUSIONS

Efficacious delivery of drugs in the eye is dependent on a host of factors including activity at the receptor, absorption and penetration of the drug for the site of application, clearance rates from the biological compartment, delivery rate and duration of the drug from the site of application, toxicology of the total dosage form, and patient compliance with the dosage form. The evolution of acceptable systems as drug carriers in the eye is usually influenced simultaneously by several of these factors. Solution or suspension drops and ointments still remain the first line approach to treatment in standard therapies. However, in circumstances demanding less frequent dosing, or dosing into less accessible compartments of the eye, more unique approaches are indicated. In those cases, use of gelling, eroding or non-eroding polymer systems has proven to be of significant value.

DRUG DELIVERY—NASAL ROUTE

René Bommer

E. Pfeiffer GmbH, Radolfzell, Germany

INTRODUCTION

Today, nasal drug delivery is receiving much attention from the pharmaceutical industry. About 2% of the overall drug delivery is administered via the nasal route. A survey (1) among decision makers in the pharmaceutical industry highlights the importance of this delivery mode. A transmucosal drug delivery route (which includes the nasal route) can target tissue and use active transdermal processes. It is also regarded as a major influence of the market.

In addition, the most popular view of nasal drug delivery is the administration of locally acting products. Topical decongestants or anti-inflammatory drugs used to treat a rhinitis or allergy related indications are well-known drug products. They expand their effect directly at the focus of the disease.

On the other hand, the nasal route is an attractive alternative to invasive administrations, and provides a direct access to the systemic circulation. Certain drugs that are administered intranasally are able to penetrate the nasal mucosa and enter the system. Intranasal application of drugs or pharmacologically active compounds has been a subject of medical knowledge since the beginning of human civilization. In India, ayurvedic medicine uses the advantage of the nasal route. Sniffing tobacco or hallucinogens is used widely throughout all cultures in the world. A rapid onset of action is one advantage of the nasal route for the administration of systemically acting products.

The attractiveness of this noninvasive route is clearly reflected in the increase of approval rates over the past few years. Locally acting products have an average growth rate of approximately 10% per year. The growth rate of systemically acting products is approximately 30%. It is remarkable that more than half of the systemically acting products were approved during the 1990s (2).

The administration of systemically acting products via the nasal route began in the 1980s. The peptide oxytocin, which stimulates uterine contraction and lactation, was one of the first nasally administered peptide hormones. Meanwhile, several peptide-based nasal formulations entered the market. Currently, more attention is being

paid to this delivery system due to the increasing demands of new highly potent drug formulations. In addition, patients' expectations for successful therapy have to be considered. Today's requirements for nasal delivery systems include three key elements: Reliability, safety, and efficacy. These must be taken into account in the development of dispensing systems for locally acting products and systemically acting products.

Nasal drug delivery devices can be divided into multidose and unit-dose/bi-dose systems. Multidose systems consist of a container mounted with a mechanical pump dispenser that is designed to deliver multiple doses from one container (Fig. 1). The various requirements of the customer and of the formulation are respected in the design and performance of the delivery systems. Unit-dose and bi-dose systems are becoming increasingly attractive to the pharmaceutical industry. In particular, therapies that require precise performance in their delivery system employ these single/dual-use disposable systems.

The nose, or more precisely the nasal cavity, is the target of the administration of a drug product. The anatomy and the physiology of the nose play a decisive role in efficient drug administration. The nasal mucosa is much more sensitive to external influences than the digestive mucosa in the stomach. On the other side, nasal administration often requires a smaller amount of drug; therefore, fewer side effects are expected. Nasal administration has several advantages. First, deposition of an active compound in the nasal cavity results in avoidance of its degradation through the "first-pass" metabolism. Second, enzymatic breakdown of the drug in the nose can be neglected. Third, the onset of action of the drug is more rapid and even comparable to an invasive route.

NASAL ANATOMY AND PHYSIOLOGY

The nose actively contributes to two major functions of the human system. The first function is the sense of smell (olfaction) and the second is respiration or breathing.

The nasal septum divides the nasal cavity into left and right halves. The nasal septum is never a straight vertical

Fig. 1 Various multidose systems.

separation of the two cavities. Through normal growth and development, the nasal septum folds together and creates an asymmetry of the two cavities, which results in variations from individual to individual. It is important to realize that the nasal cavities are not round hollow bodies; instead, they are long high slits. The nasal septum is not very accessible for the penetration of drugs into the human system since it consists mostly of cartilage and skin. The most efficient area for drug administration is the lateral walls of the nasal cavity, which consist of highly vascularized tissue, the mucosa.

The surface of the nasal cavity is approximately 150 cm². Inside the cavity, the mucosa is covered with the ciliary epithelium. The ciliary activity is the driving force of the secretory transport in the nose. Approximately 1 L of mucus is transported from the anterior part to the posterior part of the nose per day. The mucus in the rear of the cavity is removed by swallowing. The function of the ciliary activity is to remove any particles that are trapped on the mucus blanket during inhalation. It takes approximately 20–30 min for the whole mucus layer to be renewed.

The nasal mucosa is a natural site for the perception of environmental influences. The nose, with its numerous circulatory and secretory activities, is perfectly qualified for reflex conditioned reactions. One of the most remarkable autonomic reflexes is the so-called nasal cycle. Most people have a cyclic increase in the resistance of one nasal passage. However, the overall resistance remains constant. This variation is due to the swelling of the turbinates. The swelling and subsequent clogging of one nasal passage underlies a cycle time of approximately 4 h. The nose is a very complex organ. For an effective administration of

therapeutic drugs through the nasal mucosa, the following must be taken into consideration (3):

- The method and technique of administration
- The site of drug deposition
- The rate of clearance through the ciliary activity
- The pathological condition of the nose

TRADITIONAL NASAL DISPENSING SYSTEMS

Traditional application systems consist of nasal drops, pipettes, or squeeze bottles. The use of pipettes and nasal drops may work for certain drug formulations but the benefit in terms of reliability, safety, and efficacy is controversial. From an anatomical viewpoint, nasal drops may be suitable for infants only. Since the nasal cavity of an infant is so small, one or two drops can cover the whole mucosa. From the pharmacological viewpoint, the administration of drops to infants and children is controversial. For example, due to insufficient dosing accuracy, scientists do not recommend administering steroids as nasal drops to children (4). In adults, drops into the nasal cavity mostly lead to a rapid clearance of the drug along the floor of the nasal cavity toward the throat. Studies demonstrate a longer duration of sprayed products on the nasal mucosa than formulations administered as drops (5). To achieve a comparable administration mode in adults, the whole nasal cavity has to be flooded with an amount of 20–30 mL. This is pharmacologically not realistic, nor is it acceptable to the patient.

The squeeze bottle was an improvement in the deposition of drugs. The expelled spray-like product is able to reach a larger surface of the nasal mucosa than a drop. One of the major disadvantages of the squeeze bottle is its dose variability. The spray volume and plume geometry, i.e., spray angle and particle size distribution, are highly dependent on the pressure put on the bottle. In addition, the dosage and the plume geometry are influenced by two features present in a squeeze bottle, namely, the liquid formulation and the air. During the period of use, the liquid level in the container decreases and therefore, the ratio of liquid and air changes. The result is a variable spray performance that changes from one actuation to the next. Due to its unreliable performance, squeeze bottles are not recommended for administration of vasoconstrictors to children (6).

A squeeze bottle is regarded as an “open” system. There is no valve or similar mechanism that seals acceptably and prevents contamination of the contents.

The nasal tip, which is usually in contact with the nostril during actuation, naturally becomes contaminated. After releasing the pressure on the bottle, the back flow of the liquid enables bacteria to enter the system. After appropriate incubation time, contamination will occur in the container. Of course, preservatives do oppose the bioburden, but the efficacy of a preservative is limited.

Today's high potency drugs, intended for local and systemic treatments, depend on reliable delivery systems. As an alternative to squeeze bottles and pipettes, propellant-driven or mechanical-dispensing systems are often used. Aerosol systems are well known in inhalation therapy. They are ready to use and easy to handle. While new propellants will replace the old ones, the environmental and pharmacological discussions will continue. The switch to new propellants must be supported by sufficient clinical and toxicological data. In particular, compatibility problems must be addressed. Furthermore, attention must be paid to the surfactants not under dispute.

For the consumer, the sensation of a cold puff into a nostril, with resulting irritation through surfactants and propellants, is not appreciated. A further disadvantage of pressurized systems is the power of the impact of the drug formulation on the nasal mucosa. The deposition occurs on a relatively limited area and therefore, the drug is not distributed evenly over the mucosa. Studies recommend that two doses be administered at different angles into the nostril in order to cover a sufficient area of the mucosa (7). It is recommended that physicians instruct their patients on the proper use of prescribed nasal aerosols.

MECHANICAL DISPENSING SYSTEMS

Mechanical dispensing systems are an alternative to pressurized systems. The devices are not limited to spray solutions. The range of available designed actuators means that suspensions, creams, ointments, and gels also can be dispensed.

The heart of any mechanical dispensing system is its basic pump, or the motor (Fig. 2). At the bottom of the pump is a dip tube, which is the connection to the formulation in the container. An actuator is mounted on the top of the pump. Before using the mechanical dispensing system, a number of priming strokes are required to displace the air in the system and to fill the volume chamber with the targeted nominal volume. A major functional group consists of the preassembly, a combination of the moveable parts inside the pump system. As the preassembly is pushed down during

Fig. 2 Mechanical basic pump.

actuation, it compresses the spring and forces the ball into the ball seat. The increasing pressure on the liquid inside the volume chamber opens a valve mechanism and releases the amount of drug formulation through the actuator. The backstroke creates a certain vacuum in the metering chamber. The vacuum lifts the ball out of the ball seat and allows the product to refill the pump system via the dip tube.

Different kinds of pump mechanisms are on the market. Essentially, they follow the same principles. The first step is priming, or filling the volume chamber in the pump through suction. The second step is the displacement of the desired amount in the volume chamber. The third step is the actual dispensing.

Depending on a patient's requirements, the pump dispenser can be fixed to the container via a variety of different closures, such as screw closure, crimp, or snap-on. The most important parameters that define the performance of the dispensing system are the dosage volume, the spray angle, and the particle size distribution. Today, the dispensing industry offers a broad range of dosage volumes, from 25 to 1000 μL . The dimension of the metering chamber of the respective pump (Fig. 2) determines the dosage volume.

Parameters that most influence the behavior of a spray are the viscosity, the thixotropy, the surface tension, and

Fig. 3 Cross-section of a nasal actuator.

the density. Modification of the swirl chamber and the inlet channels makes it possible to adjust the spray performance to the patient’s requirements (Fig. 3). The particle size distribution can be altered by varying the dimensions and the geometry of the orifice, as well as the pressure build-up in the volume chamber prior to dispensing. One of the major criteria is to keep the fraction of extremely small particles very low to avoid partial inhalation of the drug formulation.

The increasing demands of the pharmaceutical industry have led to improvements in existing devices and the completion of new concepts.

Different consumer needs, whether for infant, child, or adult, varies the concentrations of the active ingredients in a nasal drug formulation. Fig. 4 shows a typical nasal spray

Fig. 4 100 µL nasal spray system with snap-on closure.

Fig. 5 50 µL Nasal spray system with crimp closure.

system fitted with a snap-on closure. The dispensing system can be adapted to the anatomy of the patient. The actuators for pediatric application are slimmer in their geometry and the dosage volume is reduced (Fig. 5).

Finger flanges have been modified to meet the requirements of elderly people who suffer from arthritis or rheumatism. Actuators can be adapted to deliver drug formulations to animals for veterinary purposes or for preclinical studies. Delivery systems can be fitted out with an upside down pump, which allows actuation in upright and upside down position.

A dispensing system fitted with a counting mechanism also is available (Fig. 6). It allows the consumer to monitor each actuation, beginning from the first priming stroke until delivery of the last dose. A dispensing system for

Fig. 6 Nasal spray system with integrated counting mechanism.

controlled substances, such as morphine, can be equipped with a lock-out system. The microchip controlled actuation mode takes into account the patient's specific requirements, such as amount of drug and frequency of administration. Other relevant data are recorded and can be evaluated later by a physician.

PRESERVATIVE-FREE SYSTEMS

A current trend is the development of nasal formulations without preservatives. In long-term treatments, the frequent delivery of preservatives has an irritating effect on the ciliary activity of the nasal mucosa. Economical reasons also play a key role. By reformulating an existing product, a pharmaceutical company can achieve patent extension. The challenge is to create a dispensing system that prevents a preservative-free formulation from being contaminated during the period of usage.

Different systems of preservative-free mechanical pump dispensers are now available. Basically, the prevention of contamination can be achieved in two ways—a chemical and a mechanical way. The implementation of chemical additives in the dispensing system has the advantage of reliable action of the additive. However, most of the additives that are regarded as safe “disinfectants” are not totally effective against certain strains of bacteria or fungi. With a purely mechanical preservative-free system, the contamination source remains independent. A special mechanism, inserted in the nasal actuator, seals at the very end of the tip (Fig. 7). Through actuation of the pump and due to the fact that liquid cannot be compressed, a certain hydraulic pressure is built up in the nasal actuator. As soon as the hydraulic pressure is higher than the spring force, the sealing pin will be forced backward and the liquid is dispensed via the orifice. The combination of high pressure and a small diameter of the orifice allows the liquid to leave the dispensing system at a very high velocity. A possible contamination source has to swim against the flow, which is realistically not possible. This sealing system offers not only protection against contamination but also prevents the evaporation of the remaining drug solution and a subsequent precipitation or crystallization of the solid ingredients in the actuator.

One feature of the preservative-free system is that contamination is prevented from entering the packaging from the actuator. When dispensing from an airtight container, a vacuum will be built up in the system. Two options can be used to keep the pressure balance. Either a form of ventilation is installed or the container adapts itself

Fig. 7 Preservative-free system.

to the decreasing volume. In the first option, the airflow passes a microbiological filter before entering the container (Fig. 7). In this case, the conventional gasket is replaced with a gasket made of gamma-radiation-resistant material. The filtering gasket prevents any contamination from entering the system (8). The second method employs a collapsible bag or a sliding piston. However, the collapsible bag has to be investigated carefully with regard to compatibility with the formulation and possible permeability of the product through the packaging. Because the rubber formulations and glass that are available for the sliding piston system are already used in syringes, the pharmaceutical industry might prefer this method to the multilayer collapsible bag. The sliding piston glass container, in combination with a tip-sealing mechanism on the actuator, gives the advantage of a preservative-free and airless dispensing system (Fig. 8). From the consumer's point of view, this system offers the advantages of a residual volume, which can be neglected, and in particular, a 360° performance.

Fig. 8 Preservative-free and airless system.

UNIT-DOSE AND BI-DOSE SYSTEMS

Unit-dose and bi-dose systems are designed to deliver one or two doses into the nostril(s) (Fig. 9). As compared to

multidose pump systems, unit-dose and bi-dose systems are distinguished by a different actuation principle. The dose volume is predetermined by the prefilled glass vial and sealed with a rubber stopper. The glass and rubber are the identical materials used in syringes. The benefit is an optimal protection against environmental influences. Unit-dose and bi-dose systems can be sterilized, and an aseptic filling procedure justifies the omission of preservatives. A pressure-point-controlled actuation mechanism, which builds on the inertia of the actuation finger, guarantees constant performance in terms of delivery volume, plume geometry, and particle size distribution. A manipulation of the spray performance is almost impossible.

Referring to the key words of nasal delivery systems—reliability, safety, and efficacy—the unit-dose and bi-dose dispensing systems meet these demands to the highest degree. In addition, these attributes are a versatile tool for quality control. The pressure point controlled actuation mechanism allows the spray to be independent of the user. Therefore, quality inspection will deliver more reliable results since influence from any individual, in this case the quality inspector, is almost impossible. The patient appreciates the features of a ready, easy-to-use device. The package is small in size, discrete, and works in every position. Another advantage is individual brand recognition due to the many design types on the market.

For delicate drug formulations, the industry offers a modified unit-dose system. The lyophilized ingredient(s)

Fig. 9 The unit-dose system and the bi-dose system.

are stored separately from the solvent. Prior to administration, the drug formulation is reconstituted and ready to be dispensed.

POWDER DISPENSING SYSTEMS

Nasal drug delivery is not limited to liquid drug formulations or suspensions. Powder dispensing systems can be more advantageous in dispensing many drug substances. In particular, the biotechnological drugs, mostly represented by proteins and peptides, are more stable in a dry and solid state. Studies demonstrate longer remaining times of powder formulations on the nasal mucosa as compared to liquid formulations (9). The nasal powder processing in terms of the particle size distribution is not nearly as dramatic as it is for dry powders intended for inhalation.

Recently, nasal powder vaccines have been investigated. Vaccines are usually formulated as liquid injectables or as lyophilized powder, which have to be reconstituted prior to administration. A high percentage of the world's vaccines have to be discarded due to the uncertainty of their potency after breaks in the cold chain and possible damage from exposure to high temperatures (10). Regarding physical stability, a dry solid formulation ensures a much higher stability against environmental influences. Influenza vaccines, which are administered via the nasal mucosal route, offer the pharmacological benefit of a mucosal response followed by a seric response.

Nasal dry powder delivery systems can be divided into passive and active systems. Passive systems are powder devices where the act of sniffing delivers the powder. An active system is based mostly on an air pressure driven mechanism. The powder is dispensed through a rapid airflow, which passes through the container and carries the drug into the nasal cavity. A nasal dry powder device takes advantage of the fact that one of the functions of the nose is the filtering of pollutants. A recently developed passive dry powder bi-dose system (Fig. 10) consists of two prefilled blisters, which assures optimal protection against vapor transmission, oxygen, and light. The aerodynamic feature, combined with easy actuation mode, facilitates accurate dosing in terms of expelled amount and inhalation forces. An optimal coverage of the mucosa is facilitated through a very low airflow resistance of the device. It is very convenient for the patient to sniff the powder out of the blister. As soon as the velocity of the inhalation airflow reaches 8 L/min or more, the airflow in the nasal cavity becomes turbulent (11). The turbulence in the nasal cavity

Fig. 10 Powder bi-dose system.

allows the powder to become evenly dispersed, which contributes to an optimal therapeutic effect.

The particle size of nasal powders is not regarded as critical as for inhalation powders. For inhalation, the particle size should be in the range of 1–5 μm . To allow deposition in the nasal cavity, this fine particular fraction must be avoided. The possibility of inhaling particles larger in diameter than 10 μm , or less than 5 μm , is unlikely.

Active systems are fitted with a mechanism that allows pressure to build up and eject the powder into the nostril. These devices are especially suitable for children, where it may be difficult to carry out the required inhalation process.

NASAL FORMULATIONS AND PHARMACOLOGY

During the 1990s, various nasally administered products were approved and entered the market. These included locally acting products, in particular systemically acting products (12). Most of the active ingredients are not newly discovered molecules but are reformulated products taken in the past orally or as injectables.

The benefits of nasally delivered products are their rapid onset of action under avoidance of gastrointestinal breakdown and first-pass metabolism. Furthermore, nasal drugs can be administered at a lower dose, which also means fewer side effects. Other benefits include economical reasons, such as the extensions of patents and intellectual property rights, the economic efficiency of the healthcare systems, and of course, patient compliance.

For a successful nasal product, the drug properties, the delivery system, and the nasal physiology have to act together from the early stage of the development. The development of locally acting products has to focus in

particular on a minimum of absorption into the nasal mucosa and a maximum residence time on the nasal mucosa. Systemically acting products require an efficient absorption into the bloodstream for an optimal bioavailability. It is believed that the possible transport routes of hydrophilic macromolecular compounds are paracellular, and for lipophilic compounds transcellular (13). The delivery system has to be adapted to the formulation in order to enable an optimal deposition in the nasal cavity. As the product is carried in a complex organ, researchers have to be familiar with the nasal anatomy and physiology.

Recently, a comparison study (14) of deposition pattern of aqueous nasal spray pumps and non-portable nebulizers was published. The obtained controversial results showed a relative standard deviation of 35–80%. This demonstrates the variations in nasal anatomy and physiology from individual to individual. Other studies (15) indicate that differences in the spray performance, i.e., spray angle and particle size distribution, of delivery systems do not necessarily result in different in vivo deposition.

Scintigraphic studies (16) demonstrate that the spray angle has almost no influence on the deposition pattern in the nasal cavity. Different nasal characteristics also have to be considered in the interpretation of animal studies. A comparison of interspecies characteristics was summarized by Gizurarson (17).

As mentioned previously, one of the major benefits of nasal drug delivery is the rapid onset of action (t_{\max}). Migraine treatment takes advantage of this fact. Compared to the orally taken tablet, t_{\max} is much shorter. The neurosecretory hormone melatonin, which is used widely against jetlag, shows a very impressive time profile when administered as a nasal spray (18). The peak levels of melatonin after nasal administration appear to be 50 times higher than after oral administration (19).

Lately, the nasal route is receiving attention for the management of postoperative pain. Mucosal administration requires only a 1.1–1.5 times higher dose of fentanyl than the intravenous dose (20). For this new application field, called PCINA (patient-controlled-intra-nasal-analgesia), the pharmaceutical industry demands safety precautions of the delivery device, which can be fulfilled through implementation of intelligent microelectronic features.

The nasal delivery of vaccines is a very attractive route of administration in terms of efficacy and consumer friendliness. A population-wide immunization against influenza has yet to be achieved. The pain of injections discourages many people from receiving a flu shot. The nasal route offers the advantage of a mucosal response followed by a seric response, and has proved to be a very efficient mode of administration (21).

CONCLUSIONS

Worldwide sales of pharmaceuticals in nasal form are approximately \$8 billion. The latest research in drug development for products delivered via the nasal route show very promising results. Not only is the development of “new” drugs taken into consideration, but the reformulation of products already on the market is also taken into account. The development time of a new chemical entity (NCE) is approximately 10–14 years, whereas the nasal reformulation of an existing drug is 4–5 years.

Device technology for nasal pharmaceuticals is becoming more sophisticated, which results in closer communication with regulatory authorities. For a product to be successful, the pharmaceutical industry and the device industry must begin communication at a very early stage of the product’s development. On average, launching a new drug product one year earlier will yield up to 30% more in profit.

The medical device industry has developed many ways to dispense nasal formulations. Device technology is becoming more and more important, not only with regard to pharmacological issues, such as efficacy or safety, but also in terms of responding to healthcare driven trends and marketing aspects, such as patient compliance or brand recognition. After careful evaluation of all aspects, the consumer can be provided with an appropriate nasal drug delivery system for an efficient therapy. The pharmacological issues of the nasal route for systemic drug delivery are widely discussed in the references (3, 6, 22).

DRUG INTERACTIONS

Daniel A. Hussar

University of the Sciences in Philadelphia, Philadelphia, Pennsylvania, U.S.A.

DRUG INTERACTIONS

The term *drug interaction* is applied most frequently to those situations in which the actions of one drug are altered by the concurrent use of another (drug–drug interactions), and to those situations in which the actions of nutrients affect drugs or vice versa (drug–nutrient–food interactions). The concept of drug interaction has also been extended to include situations in which a drug causes alterations of laboratory test results (drug–laboratory test interactions) and in which a drug causes undesired effects in patients with certain disease states (drug–disease interactions).

CONSEQUENCES OF DRUG INTERACTIONS

One of the most important consequences of a drug interaction is an excessive response to one or more of the agents being used. For example, a significantly enhanced effect of agents such as digoxin (e.g., Lanoxin) and warfarin (e.g., Coumadin) can result in serious complications, and the hazards of using agents having central nervous system depressant properties in combination are also well known. Not as well recognized but also very important are those interactions in which drug activity is decreased, resulting in a loss of efficacy. These interactions are especially difficult to detect because they may be mistaken for therapeutic failure or worsening of the disease.

Although some drug interactions develop unexpectedly and are impossible to predict, others are related to known pharmacodynamic and pharmacokinetic properties of the drugs and can be anticipated. However, in considering the number and diversity of the pharmacological actions of each of the agents utilized in many multiple-drug regimens, it is very difficult to predict the magnitude of a specific action of any given drug. These circumstances point to a need not only for maintenance of complete and current medication records for patients, but also for closer monitoring and supervision of drug therapy so that problems can be prevented or detected at an early stage.

The concerns over drug interactions and the advocacy for appropriate precautionary measures are justifiably

based on the rapidly growing number of observations and studies in which these problems have been described. However, it is also very important to keep in perspective the potential for the occurrence of an interaction. Caution is needed in evaluating and using the available information to avoid overreacting to a potential problem. Although therapeutic alternatives might be considered and/or steps taken to more closely monitor combination therapy, patients must not be deprived of therapy from which they can benefit. The appropriate clinical perspective must be exercised if optimal therapy is to be achieved.

Sometimes a second drug is prescribed intentionally to modify the effects of the first. Such an approach might be used in an effort to enhance the effectiveness or to reduce the adverse effects of the primary agent. In these situations, the efficacy and/or safety of a drug is increased, which indicates that drug interactions are not always harmful but also can be beneficial.

FACTORS CONTRIBUTING TO THE OCCURRENCE OF DRUG INTERACTIONS

A number of factors contribute to the occurrence of drug interactions; the most important factors will be discussed.

Multiple Pharmacological Effects

Most drugs used in current therapy exhibit more than one type of pharmacological action and have the capacity to influence many physiological systems. Therefore, two concomitantly administered drugs will often affect some of the same systems. When considering the potential for interactions between drugs, there is often a tendency to focus on the primary effects of the drugs involved and to overlook their secondary actions. As an example, combined therapy with a phenothiazine antipsychotic [e.g., chlorpromazine (Thorazine)], a tricyclic antidepressant [e.g., amitriptyline (e.g., Elavil)], and an antiparkinsonian agent [e.g., trihexyphenidyl (e.g., Artane)] is employed in some patients. Each of these agents has a considerably different primary effect; however, all three possess anticholinergic activity. Even though the

anticholinergic effect of any one of the drugs may be slight, the additive effects of the three agents may be significant.

Multiple Prescribers

Some individuals go to more than one physician, and it is common for a patient to be treated by one or more specialists in addition to a family physician. Some patients are also seeing other health professionals (e.g., dentists, podiatrists, etc.), who may prescribe medication. It is frequently difficult for one prescriber to become aware of all the medications that have been prescribed by others for a particular patient, and many difficulties arise from such situations. For example, one physician may prescribe an antihistamine having sedative properties for a patient for whom another physician has prescribed an antianxiety agent, with the possible consequence of an excessive depressant effect. Even though the patient is seeing different prescribers, he will often have the prescriptions dispensed at the same pharmacy. Therefore, the pharmacist, by maintaining patient medication records, plays an important role in the detection and prevention of drug-related problems.

Concurrent Use of Nonprescription Drugs

Many reports of drug interactions involve the concurrent use of a prescription drug with a nonprescription drug (e.g., aspirin, antihistamines, antacids, etc.). When a physician questions a patient about medications being taken, the patient will often neglect to mention nonprescription medications. Many patients take preparations such as antacids, laxatives, analgesics, and vitamins for such long periods and in such a routine manner that they do not consider them to be drugs. This information may often be missed when questioning patients, and some physicians and pharmacists prefer to utilize a list of symptoms that might ordinarily be treated with nonprescription drugs when obtaining this information from patients.

Interactions may also result from the concurrent use of two or more products available without a prescription. In some situations, two nonprescription products promoted for different purposes contain the same active ingredient(s), which increases the risk of an excessive response to these agents. Diphenhydramine is included in many products for its antihistamine action but also is included for its sedative effect in many nonprescription sleep aids. Patients are often unaware that the products they purchase for different conditions may contain the same active ingredients. This puts users at increased risk for interaction

difficulties due to the use of products they assume are safe since they do not require a prescription.

The observations made with respect to potential interactions involving nonprescription products also apply to the use of herbal products, dietary supplements, and other related products that are available without a prescription. Although much is still to be learned about the properties of these products, many appear to have a potential to interact with prescription medications. Therefore, patients should be asked whether they are using such products.

Patient Noncompliance

For a variety of reasons, many patients do not take medication in the manner intended by the prescriber. Some patients have not received adequate instructions from the prescriber and pharmacist as to when and how to take their medication. In other situations, particularly those involving patients who are taking several medications, confusion about the instructions may develop even though the patient understood them initially. It is understandable that older patients, who may be taking five or six medications several times a day at different times, can become confused or forget to take their medication, although these occurrences are by no means unique to this population.

At times, patients are noncompliant when they do not take enough of their medication. In other instances, interactions can occur due to excessive dosing. For example, some patients double their dose of medication after realizing they forgot to take the initial dose. Other patients may assume that if the prescribed one tablet dose provides partial but not complete relief of symptoms, a two-tablet dose will be more effective.

MECHANISMS OF DRUG INTERACTION

Understanding the mechanisms by which drug interactions develop will be valuable in anticipating such situations and dealing with problems that do develop. Although the circumstances surrounding the development of some drug interactions are complex and poorly understood, the mechanisms by which many interactions develop are well documented and relate to the basic processes by which drugs act and are acted on in the body.

These mechanisms are often generally categorized as being either pharmacodynamic or pharmacokinetic. Included among the pharmacodynamic interactions are those in which drugs that have similar (or opposing) pharmacological effects are administered concurrently and

situations in which the sensitivity or responsiveness of the receptors/tissues to one drug is altered by the action of another. In these situations, there is a change in drug effect without a change in drug plasma concentration. Pharmacokinetic interactions are those in which one agent (designated by some as the “precipitant drug”) alters the absorption, distribution, metabolism, or excretion (ADME) of a second agent (the “object drug”), with a resultant change in the plasma concentration of the latter agent. Several mechanisms may be involved in the development of certain interactions.

Pharmacodynamic Interactions

Although pharmacokinetic interactions have been studied and publicized to a greater extent, pharmacodynamic interactions are very common and also present challenging clinical problems. Some of the causes of pharmacodynamic interactions will be discussed.

Drugs having opposing pharmacological actions

Interactions resulting from the use of two drugs with opposing effects should be among the easiest to detect. However, opposing pharmacological actions are sometimes caused by the secondary effects of certain drugs, and this and other factors may preclude early identification of such situations.

Diuretics: Thiazides and certain other diuretics may elevate blood glucose concentrations. When the diuretic is prescribed for a diabetic patient being treated with insulin or one of the oral antidiabetic agents, this effect may partially counteract the glucose-lowering action of the antidiabetic drug, necessitating an adjustment in dosage. Similarly, many diuretics may produce a hyperuricemic effect. Therefore, therapy in patients with gout should be closely monitored, as the hyperuricemic action of a diuretic may necessitate an adjustment in dosage of the agent being used in the treatment of gout.

Drugs having similar pharmacological actions

The most common type of pharmacodynamic interaction is an excessive response attributable to the concurrent use of drugs having similar actions. These potential problems warrant particular attention.

Central nervous system (CNS) depressants: An excessive CNS depressant effect, resulting from the concurrent use of two or more drugs exhibiting a depressant action, represents one of the most dangerous drug related problems. Older patients are especially susceptible to this type of response, and patients experiencing effects such as fatigue and dizziness are at increased risk of falls and injuries, such as hip fractures. Patients also must be advised

of the risks of operating motor vehicles or machinery. In considering multiple drug regimens, the prescriber needs to recognize the large number of agents (e.g., antianxiety agents, hypnotics, antipsychotics, tricyclic antidepressants, certain analgesics, and most antihistamines) that can exhibit a depressant effect. Consideration should be given to whether it is necessary to use all the drugs concurrently, and the dosages of the drugs having a depressant effect should be appropriately reduced.

Alcohol and other CNS depressants: The increased CNS depressant effect experienced by most individuals being treated with depressant drugs when they consume alcoholic beverages is among the best known interactions. However, this interaction also illustrates the difficulties in predicting the magnitude of the response experienced by a particular patient, as the response will depend on many variables, including the patient's tolerance of alcohol. Every patient should be alerted to the fact that the depressant effect of the drug prescribed may be enhanced by alcohol. Patients who will not completely avoid alcoholic beverages should be urged to use them only in moderation, particularly when therapy is initiated, and cautioned to observe their own tolerance when such combinations are employed. However, it should be remembered that even though many individuals can take depressant drugs and consume relatively large amounts of alcoholic beverages with no apparent difficulty, this combination can be lethal to some and cause injury to others. Thus, all patients prescribed these drugs need to be warned of the potential interactions.

Drugs having anticholinergic activity: As noted earlier, drugs that differ considerably in their primary pharmacological actions may exhibit the same secondary effects. Some patients treated with antipsychotic agents, such as chlorpromazine, are also given antiparkinsonian agents, such as trihexyphenidyl, to control the extrapyramidal effects of the former. In addition, a number of patients experience depressive symptoms, and a tricyclic antidepressant, such as amitriptyline, might be added to the therapy. These three agents all possess anticholinergic activity, and the additive effect could result in side effects such as dryness of the mouth, blurred vision, urinary retention, constipation, and elevation of intraocular pressure.

While some health professionals might consider side effects such as dryness of the mouth to be minor, these side effects may be especially troublesome in certain patients. For example, persistent dryness of the mouth could make the use of dentures more difficult and cause other dental complications. Increased difficulty in chewing and swallowing may contribute to the problem of malnutrition in some older individuals.

Dryness of the mouth may also result in other problems. For example, the tricyclic antidepressant imipramine (e.g., Tofranil) can cause persistent dryness of the mouth. If nitroglycerin tablets are administered sublingually for the management of exertional angina, the relief of the symptoms may be delayed due to the slower dissolution of the sublingual tablets.

An excessive anticholinergic effect can cause an atropine-like delirium, particularly in older patients. This effect could be misinterpreted as an increase in psychiatric symptoms that might be treated by increasing the dosage of the therapeutic agents that are responsible for the problem. This example points out the difficulty that often exists in distinguishing between the symptoms of the condition(s) being treated and the effects of the drug(s) being employed as therapy. Other potential problems associated with the use of drugs having anticholinergic activity include memory impairment and impairment in self-care capacity.

There have been reports of patients who take a phenothiazine and antiparkinsonian agent concurrently developing severe hyperpyrexia after being exposed to high environmental temperatures and humidity. These combinations may interfere with the thermoregulatory system of the body, and physicians treating patients in hot and humid climates should minimize the outdoor exposure of patients receiving high doses of these agents.

Drugs exhibiting hypotensive effects: Certain antihypertensive drugs, as well as some other classes of medications (e.g., tricyclic antidepressants), can cause orthostatic hypotension, which results in dizziness, lightheadedness, and in more severe cases, syncope. Older patients are more susceptible to this type of response and the associated risks, such as falls and injuries. Appropriate precautions should be exercised whether these agents are given alone or in combination.

Nonsteroidal antiinflammatory drugs (NSAIDs): In some cases, a patient may unknowingly be taking several different products that contain the same NSAID. An arthritic patient whose condition has been managed with ibuprofen obtained via prescription (often at dosage levels at or near the recommended maximum) may purchase a nonprescription ibuprofen product for pain/discomfort not associated with the arthritis. The patient may not know that the two products contain the same drug and that there is an increased risk of adverse effects.

Alteration of electrolyte concentrations

Several important drug interactions occur as a result of therapeutic agents altering the concentrations of electrolytes, such as potassium and sodium. When these drugs are included in a therapeutic regimen, it is important that electrolyte concentrations be periodically monitored.

Digoxin and diuretics: One of the problems associated with the use of most of the commonly employed diuretics [e.g., the thiazides furosemide (e.g., Lasix)], is excessive loss of potassium. Particular caution is necessary in patients also being treated with digoxin, many of whom are also candidates for diuretic therapy. If potassium depletion remains uncorrected, the heart may become more sensitive to the effects of digoxin and arrhythmia may result.

Although potassium supplementation is necessary in some individuals being treated with a potassium-depleting diuretic, the initiation of therapy with such a diuretic must not be viewed as a mandate to provide potassium supplementation. This decision should be based on a consideration of the individual patient's situation and the appropriate parameters should be periodically monitored. It must be recognized that dangers exist if hyperkalemia occurs as a result of excessive supplementation. Although the kidneys are usually able to excrete excessive amounts of potassium rapidly, hyperkalemia may develop, especially in patients with diminished renal function.

In addition to the diuretics, other agents can cause potassium depletion. Prolonged therapy with cathartics and corticosteroids can cause potassium depletion, although this is not likely to occur as quickly or to the same extent as with diuretics.

Lithium and diuretics: Sodium depletion is known to increase lithium toxicity, and it is generally recommended that lithium not be used in patients on diuretic therapy or on a sodium-restricted diet. Even protracted sweating or diarrhea can cause sufficient depletion of sodium to result in decreased lithium tolerance. The sodium depletion caused by diuretics reduces the renal clearance and increases the activity of lithium. However, if preferable therapeutic alternatives are not available, concurrent therapy need not be contraindicated as long as the interaction is recognized and appropriate steps are taken to monitor therapy and adjust the dosage.

Interactions at receptor sites

Examples of interactions occurring at receptor sites include problems involving the use of the monoamine oxidase (MAO) inhibitors [isocarboxazid (Marplan), phenelzine (Nardil), tranylcypromine (Parnate), and procarbazine (Matulane)].

MAO inhibitors and sympathomimetic agents: MAO breaks down catecholamines, such as norepinephrine. When this enzyme is inhibited, the concentrations of norepinephrine within adrenergic neurons increase and drugs that stimulate its release can bring

about an exaggerated response. Interactions between MAO inhibitors and indirectly acting sympathomimetic amines (e.g., amphetamine) develop by this mechanism. If amphetamine is administered to a patient whose stores of norepinephrine have been increased by MAO inhibition, the patient may experience severe headache, hypertension (possibly a hypertensive crisis), and cardiac arrhythmias. The serious consequences associated with these interactions contraindicate the use of these agents in combination.

Most sympathomimetic amines, such as amphetamine, are available only by prescription; others such as phenylephrine and pseudoephedrine, which also are reported to interact similarly with MAO inhibitors, are found in most popular nonprescription cold and allergy preparations. It is important that patients being treated with MAO inhibitors avoid using products containing these agents.

MAO inhibitors and other antidepressants: Product literature and case reports caution against concurrent use of MAO inhibitors with tricyclic antidepressants (e.g., amitriptyline, imipramine) because severe atropine-like reactions, tremors, convulsions, hypothermia, and vascular collapse can occur. The labeling for most of these products warns that therapy with a MAO inhibitor or a tricyclic antidepressant should not be initiated until at least 7–14 days after therapy with the other drug has been discontinued.

Although the labeling for most MAO inhibitors and tricyclic antidepressants warns that concurrent use is contraindicated, there is disagreement as to the degree of risk involved. Several studies show little evidence of interaction. The impression that serious interactions are uncommon, coupled with reports of favorable results with such combinations in selected patients who did not respond to either agent given alone, have led some to conclude that these combinations can be cautiously employed. In patients who are refractory to single antidepressants and who are not candidates for other therapeutic approaches, the potential benefits of combination therapy may outweigh the risks. However, such therapy should be undertaken only by those who are thoroughly familiar with the risks involved and under circumstances in which therapy can be closely monitored.

Very little data regarding the combined use of fluoxetine (Prozac) and a MAO inhibitor are available. It is advised that their combined use be avoided and that at least 14 days elapse between discontinuation of a MAO inhibitor and initiation of treatment with fluoxetine. There are reports of deaths in patients in whom therapy with a MAO inhibitor was initiated shortly after discontinuation

of fluoxetine. Due to the long half-lives of fluoxetine and its active metabolite, it is recommended that at least 5 weeks elapse between discontinuation of fluoxetine and initiation of therapy with a MAO inhibitor.

Pharmacokinetic Interactions

Alteration of gastrointestinal absorption

The interactions that involve a change in the absorption of a drug from the gastrointestinal (GI) tract may develop through different mechanisms and be of varying clinical importance. In some situations, the overall absorption of the drug might be reduced and its therapeutic activity compromised. In other circumstances, absorption may be delayed but the same amount of drug is eventually absorbed. A delay in drug absorption is undesirable when a rapid effect is needed to relieve acute symptoms such as pain. However, in other situations, a delay in drug absorption will not be clinically significant, and this is usually the case when a drug is being used on a chronic basis and therapeutic concentrations in the body have already been achieved. As a general guideline, those drugs not completely absorbed under normal circumstances are most susceptible to alterations of GI absorption.

Ketoconazole and antacids: An acidic medium is required to achieve adequate dissolution of ketoconazole (e.g., Nizoral) following oral administration. Therefore, an antacid, histamine H₂-receptor antagonist [e.g., cimetidine (e.g., Tagamet), ranitidine (e.g., Zantac)], or a proton pump inhibitor [e.g., lansoprazole (Prevacid), omeprazole (Prilosec)] is likely to reduce the dissolution, absorption, and effectiveness of the antifungal agent. An antacid should be administered at least 2 h after ketoconazole. The concurrent use of ketoconazole and a histamine H₂-receptor antagonist or proton pump inhibitor is best avoided, and other agents having a lesser potential for interaction should be considered.

Tetracyclines and metals: Tetracyclines can combine with metal ions, such as calcium, magnesium, aluminum, and iron, in the GI tract to form complexes that are poorly absorbed. Thus, the simultaneous administration of certain drugs (e.g., antacids, iron preparations, products containing calcium salts) by patients on tetracycline therapy could result in a significant decrease in the amount of antibiotic absorbed. When two drugs are recognized as having a potential to interact, there is sometimes a tendency to believe that one of them should be discontinued. In the case of the tetracycline–antacid interactions, problems can be avoided by allowing an interval of at least 1 h to separate the administration of the two drugs.

Fluoroquinolones and metals: Aluminum- and magnesium-containing antacids, as well as other products that contain metals (e.g., iron), markedly reduce the absorption and serum concentrations of the fluoroquinolone derivatives [e.g., ciprofloxacin (Cipro)], probably as a result of the metal ions complexing with the antiinfective agent. Antacids or other metal-containing products must not be administered at the same time as a fluoroquinolone, and the labeling for most of the fluoroquinolones designates a minimum interval of time that should separate the administration of the two drugs. For example, it is recommended that moxifloxacin (Avelox) be taken at least 4 h before or 8 h after taking antacids or other metal-containing products.

Cholestyramine and colestipol: Other interactions involving complexation might be anticipated when cholestyramine (e.g., Questran) and colestipol (Colestid) are used. These resinous materials, which are not absorbed from the GI tract, bind with bile acids and prevent their reabsorption. In addition, cholestyramine and colestipol can bind with drugs (e.g., digoxin and warfarin) that are present in the GI tract. To minimize the possibility of an interaction, the interval between the administration of cholestyramine or colestipol and another drug should be as long as possible.

An interesting application of this interaction is seen with the use of leflunomide (Arava) in the treatment of rheumatoid arthritis. Leflunomide can cause fetal harm if administered during pregnancy, and it has an active metabolite that can persist in the system for at least 2 years. If a woman of childbearing potential discontinues use of leflunomide, it is recommended that cholestyramine (8 g 3 times a day for 11 days) be used to accelerate the elimination of the drug and its active metabolite.

Food: Food can influence the absorption and activity of a number of drugs. In some situations, absorption is delayed but not reduced, whereas in other circumstances, the total amount of drug absorbed is reduced. The effect of food in influencing drug absorption is often due to slower gastric emptying. However, food may also affect absorption by binding with drugs, by decreasing the dissolution rate of solid dosage forms, or by altering the pH of the GI contents.

The presence of food in the GI tract reduces the absorption of many antiinfective agents. Although there are some exceptions (e.g., penicillin V, amoxicillin, and doxycycline), it is generally recommended that penicillin and tetracycline derivatives, as well as certain other antiinfective agents, be given at least 1 h before meals or 2 h after meals to achieve optimum absorption.

Alendronate and food: Food and some beverages (e.g., orange juice, coffee, and mineral water) may markedly reduce the bioavailability of alendronate (Fosamax). Therefore, the drug should be administered at least 30 min before the first food, beverage, or medication of the day, with plain water only.

Acarbose or miglitol and food: Some medications should be administered with food for optimum benefit. Acarbose (Precose) and miglitol (Glyset) are effective in the treatment of diabetes mellitus because they delay the digestion of ingested carbohydrates and reduce the elevation of blood glucose concentrations following meals. Maximum effectiveness is attained when doses are administered at the start (with the first bite) of each main meal.

MAO inhibitors and tyramine: There have been reports of serious reactions (e.g., hypertensive crises) occurring in patients being treated with a MAO inhibitor following ingestion of foods with a high content of pressor substances, such as tyramine.

Tyramine is metabolized by MAO, and normally these enzymes in the intestinal wall and in the liver protect against the pressor actions of amines in foods. However, when these enzymes are inhibited, large quantities of unmetabolized tyramine can accumulate and act to release norepinephrine from adrenergic neurons where greater-than-usual stores of this catecholamine are concentrated as a result of MAO inhibition. Among the foods having the highest tyramine content are aged cheeses (such as cheddar), certain alcoholic beverages (e.g., Chianti), pickled fish (e.g., herring), concentrated yeast extracts, and broad-bean pods (also known as fava beans or Italian green beans).

The pharmaceutical companies that market the MAO inhibitors have developed lists of dietary items to avoid when taking one of these agents. This information should be provided to and discussed with each patient who is prescribed a MAO inhibitor.

Grapefruit juice: Grapefruit juice is reported to increase the serum concentrations and activity of a number of medications, such as certain calcium channel blocking agents [e.g., felodipine (Plendil) and nisoldipine (Sular)], certain HMG-CoA reductase inhibitors [e.g., lovastatin (Mevacor)], and cyclosporine (e.g., Neoral). The bioavailability of most of these agents is generally low, primarily as a result of extensive first-pass metabolism. Components of grapefruit juice possibly reduce the activity of the cytochrome P450 enzymes (primarily CYP3A4) in the gut wall, which are involved in the metabolism of these agents. As a result, larger amounts of unmetabolized drug are absorbed and serum concentrations are increased.

Alteration of distribution

Interactions involving an alteration of distribution may occur when two drugs that are capable of binding to proteins are administered concurrently and one agent displaces the other. Most significant are the situations in which two drugs are capable of binding to the same sites on the protein (competitive displacement). Since protein-binding sites are limited in number, the drug that has the greater affinity for the binding sites will displace the other from plasma or tissue proteins. The protein-bound fraction of a drug in the body is not pharmacologically active. However, an equilibrium exists between bound and unbound fractions, and as the unbound or “free” form of the drug is metabolized and excreted, the bound drug is gradually released to maintain the equilibrium and pharmacological response.

The risk of an interaction occurring is greatest with those drugs that are highly protein bound (more than 90%) and that also have a small apparent volume of distribution. Since only a small fraction of the drug would ordinarily be available in the free form, the displacement of even a small percentage of the amount that is bound to proteins could produce a considerable increase in activity.

Methotrexate: Methotrexate is highly bound to plasma proteins, and agents such as the salicylates may be capable of displacing it from binding sites. Salicylates may also increase the action of methotrexate by inhibiting its renal excretion. The potential for toxicity with methotrexate dictates caution in all situations in which it is used.

Stimulation of metabolism

Drug metabolism occurs primarily in the liver and most commonly involves oxidation, reduction, hydrolysis, and conjugation reactions. Quantitatively, the most important hepatic enzymes are the cytochrome P450 enzymes that have been divided into families and subfamilies (e.g., CYP3A4) based on the similarity of their amino acid sequences. These enzymes are responsible for the metabolism of a large number of drugs.

Many drug interactions result from an effect frequently referred to as enzyme induction: the ability of one drug to stimulate the metabolism of another, most often by increasing the activity of liver enzymes. Enzyme induction usually results in increased metabolism and excretion, and reduces the effect of the agent that is metabolized by the hepatic enzymes. Phenobarbital (and other barbiturates), phenytoin, carbamazepine (e.g., Tegretol), and rifampin (e.g., Rifadin) are among the agents best recognized as causing enzyme induction.

Warfarin and phenobarbital: Phenobarbital, by causing enzyme induction, can increase the rate of metabolism of warfarin. The result of this interaction is a decreased response to the anticoagulant and an increased risk of thrombus formation if the interaction is not recognized.

Smoking: The polycyclic hydrocarbons in cigarette smoke may increase the activity of oxidative enzymes, with the result that certain therapeutic agents [e.g., diazepam (e.g., Valium), propoxyphene (Darvon), theophylline, chlorpromazine, and amitriptyline] are metabolized more rapidly and their effect is decreased. In addition to monitoring therapy carefully with drugs that are metabolized by hepatic enzyme systems in patients who are moderate or heavy smokers, caution must also be exercised if a patient treated with such a medication discontinues smoking. For example, if therapy with a tricyclic antidepressant is initiated in a patient who is a heavy smoker, the maintenance dosage will be determined during the time period in which the enzyme-inducing action of smoking is decreasing the effect of the medication. If the patient stops smoking and is still taking the medication, the dosage that had been appropriate is now likely to be excessive and will have to be reduced.

Inhibition of metabolism

There are numerous situations in which one drug inhibits the metabolism of a second agent, usually resulting in a prolonged and intensified activity of the latter.

Mercaptopurine or azathioprine and allopurinol: Allopurinol (e.g., Zyloprim), by inhibiting the enzyme xanthine oxidase, reduces the production of uric acid, which is the basis for its use in the treatment of gout. Xanthine oxidase also has an important role in the metabolism of such potentially toxic drugs as mercaptopurine (e.g., Purinethol) and azathioprine (e.g., Imuran). When xanthine oxidase is inhibited by allopurinol, the effect of these agents can be markedly increased. When allopurinol is given in doses of 300–600 mg/day concurrently with either of these drugs, it is advised that the dose of mercaptopurine or azathioprine be reduced to about one-third to one-fourth the usual dose.

Cimetidine: Since cimetidine may inhibit certain metabolic pathways, an increased action of concurrently administered drugs that are metabolized via these pathways should be anticipated. For example, cimetidine may inhibit the metabolism of diazepam and certain other benzodiazepines, and the sedative effect of these agents may be enhanced as a result of the interaction. Particular caution is necessary in older patients who may exhibit an increased sensitivity to the depressant effects of the

benzodiazepines, even when one of these agents is given alone.

The metabolism of lorazepam (e.g., Ativan), oxazepam (e.g., Serax), and temazepam (e.g., Restoril) are not likely to be affected, and one of these agents may be preferred when a benzodiazepine is indicated in a patient being treated with cimetidine. The experience with ranitidine (e.g., Zantac), famotidine (Pepcid), and nizatidine (Axid) suggests that these agents are not likely to inhibit hepatic enzyme systems, and these other histamine H₂-receptor antagonists are less likely than cimetidine to interact with other drugs that are metabolized via these pathways.

Macrolide antibiotics: Erythromycin may significantly increase serum concentrations of medications such as theophylline by inhibiting their hepatic metabolism. Clarithromycin (Biaxin) and troleandomycin appear to interact with other medications in a manner similar to erythromycin, whereas azithromycin (Zithromax) is unlikely to interact with these agents.

Fluoroquinolones: Ciprofloxacin and enoxacin (Penetrex) may markedly increase serum concentrations of medications such as theophylline by inhibiting their hepatic metabolism. Certain other fluoroquinolones, such as levofloxacin (Levaquin), are not likely to inhibit hepatic enzyme systems and interact with these medications.

Alteration of excretion

Many drugs and their metabolites are excreted via the kidneys. The most important clinical implications of altering renal excretion involve the use of drugs that are excreted in their unchanged form or in the form of an active metabolite. Thus, substances with pharmacological activity are being reabsorbed or excreted to a greater extent when renal excretion is altered.

Salicylates: A change in urinary pH will influence the ionization of weak acids such as salicylates as well as weak bases (e.g., amphetamine), thereby affecting the extent to which these agents are reabsorbed and excreted. When a drug is in its nonionized form, it will more readily diffuse from the urine back into the blood. Therefore, an acidic drug will have a larger proportion of the nonionized drug in an acid urine than in an alkaline urine, where it will primarily exist as an ionized salt. The result is that acidification of the urine may result in increased salicylate concentrations and a prolonged and perhaps intensified drug action. The risk of a significant interaction is greatest in patients who take large doses of salicylates (e.g., for arthritis).

Penicillins and probenecid: A number of organic acids are actively transported from the blood into the tubular urine and vice versa. In some situations, these agents interfere with each other's excretion. Probenecid

(e.g., Benemid) can increase the serum concentrations and increase and prolong the activity of penicillin derivatives by blocking their tubular secretion. This is an interaction that has been used to therapeutic advantage in the treatment of certain infections.

Methotrexate and NSAIDs: NSAIDs are reported to increase the activity and toxicity of methotrexate, presumably by inhibiting its active renal tubular secretion. Other mechanisms probably also contribute to an increase in serum methotrexate concentrations. Most of the patients in whom these interactions were reported were receiving high-dose methotrexate therapy for neoplastic disorders. However, caution should also be exercised in patients receiving lower doses.

Digoxin and quinidine: Studies have noted significantly greater serum digoxin concentrations when quinidine was administered concurrently than when digoxin was given alone. Digoxin is actively secreted in the renal tubules, and a primary cause of the quinidine-induced increase in serum digoxin concentrations appears to be a reduction in the renal clearance of digoxin. However, quinidine may also reduce the nonrenal clearance of digoxin.

Although other mechanisms may be involved in the development of drug interactions, the ones cited are the most important. More than one mechanism may be responsible for certain interactions and these mechanisms may work in concert or in opposition to determine the resulting effect. Still other drug interactions develop by mechanisms yet to be identified.

Significant limitations often exist in trying to predict the results of combination therapy. In the following discussion, guidelines are provided to reduce the risk of the occurrence of drug interactions.

REDUCING THE RISK OF DRUG INTERACTIONS

Reducing the risk of drug interactions is a challenge that embraces a number of considerations. The following are guidelines to reduce and manage drug interactions.

1. Identify patient risk factors: Factors such as age, the nature of the patient's medical problem (e.g., impaired renal function), dietary habits, smoking, and problems such as alcoholism influence the effect of certain drugs and should be considered during the initial patient interview.
2. Take a thorough drug history and maintain complete patient medication records: An accurate and complete record of both the prescription and nonprescription medications a patient is taking must be obtained prior

- to changing the therapeutic regimen. Numerous interactions have resulted from a lack of awareness of medications prescribed by another physician, or of nonprescription medications the patient did not consider important enough to mention. By maintaining patient medication records, the pharmacist is in an excellent position to detect potential problems and initiate the necessary steps to minimize or avoid them.
3. Be knowledgeable about the actions of the drugs being utilized: The knowledge of the properties and the primary and secondary pharmacological actions of each of the agents used, or being considered for use, is essential if the interaction potential is to be accurately assessed.
 4. Consider therapeutic alternatives: In most cases, two drugs that are known to interact can be administered concurrently as long as adequate precautions are taken (e.g., closer monitoring of therapy or dosage adjustments to compensate for the altered response). However, in those situations in which another agent with similar therapeutic properties and a lesser risk of interaction is available, the other agent should be used.
 5. Avoid complex therapeutic regimens where possible: The number of medications used should be kept to a minimum. In addition, the use of medications or dosage regimens that permit less frequent administration may help avoid interactions that result from an alteration of absorption (e.g., when a drug is administered in close proximity to meals).
 6. Educate the patient: Patients often know little about their illness, let alone the benefits and problems that could result from drug therapy. Individuals who understand this information are more likely to comply with instructions for administering medications and are more attentive to the development of symptoms that could be early indicators of drug-related problems. Patients should be encouraged to ask questions about their therapy and to report any excessive or unexpected responses. There should be no uncertainty on the part of the patient as to how to use medications in the safest, most effective way.
 7. Monitor therapy: The risk of drug-related problems warrants close monitoring, not only for the possible occurrence of drug interactions but also for adverse effects occurring with individual agents and noncompliance. Any change in patient behavior should be suspected as drug-related until that possibility is excluded.
 8. Individualize therapy: Although the development of a therapeutic regimen that meets the specific needs of individual patients is inherent in many of the above guidelines, the importance of this consideration cannot be too strongly emphasized. Wide variations in the response of patients to the same dose of certain drugs are well recognized. It is difficult to predict the response to many therapeutic agents when they are given alone; the challenge and limitations in anticipating the response to a multiple drug regimen are even greater. Therefore, priority should be assigned to the needs and clinical response of the individual patient, rather than to the usual dosage recommendations, standard treatment, and monitoring guidelines.
 9. Involve the patient as a partner in health care. The best efforts of the health professionals involved in the patient's care will fall short of the desired goals unless the patient and/or the family participates in, understands, and complies with decisions regarding the therapeutic regimen. If the optimal benefits of therapy are to be achieved with minimal risk, each participant must be knowledgeable about and diligent in fulfilling his responsibilities.
- The following publications are recommended as comprehensive references in which detailed information regarding specific interactions is provided:

Drug Information Systems

Linda Lisgarten

Michelle Wake

University of London, London, U.K.

INTRODUCTION

All those with an interest in the pharmaceutical sciences need up-to-date and reliable drug information, not only for their own research and studies, but also for communicating with their healthcare colleagues and patients. In this chapter, we will discuss the wide range of modern electronic drug information systems that are currently available, and will give an indication of their main uses and individual strengths.

Since the 1960s, there has been a dramatic increase in the amount of drug information. The number of chemical compounds alone is growing at a tremendous rate. The CAS Registry database adds around 4000 new substances every day. In tandem with this huge growth of information, there have been many developments in data storage and communication technology, which have impacted on the type of medium used to contain and deliver drug information. Along the way we have used, and are still using, paper, microfilm/microfiche, magnetic tape, floppy disks, CD-ROMs, DVDs, and of course Internet servers. There has been a veritable explosion of drug information on the World Wide Web during the past few years.

Also, there are other features and peculiarities about the nature of drug information (apart from the sheer quantity) which can make it difficult to find what you need. Drugs have several names, and those names can differ from country to country: for example, the substance known as acetaminophen in the United States is known as paracetamol in the UK. Then, there is the problem of licensing arrangements which also differ from country to country: a well-known recent example of this being Viagra, which was available in the United States several months before it officially became available in the UK. (For help with nomenclature try the CAS Registry File, the Merck Index, Martindale, or Pharmaprojects. The last resource is very useful for finding out brand names and gives information on when a product was licensed in different countries.)

BACKGROUND

The sources of drug information are extremely diverse and include journals, books, conference proceedings, patents, and trade literature. These sources are generally classified

as primary, secondary, or reference compendia/tertiary information. "Primary" refers to original and new information and "secondary" refers to reviews and commentaries of the primary information, whereas "reference compendia" or "tertiary" usually refers to compilations such as dictionaries and pharmacopoeias. When conducting an information literature search, it is wisest to begin with the reference/tertiary sources as necessary and then move on to the secondary and finally the primary sources of drug information.

REFERENCE COMPENDIA

Pharmacopoeias, Compendia, and Formularies

Many queries can be answered quickly by using a pharmacopoeia, a drug compendium or a formulary. Many of these are now available electronically:

Pharmacopoeias

- United States Pharmacopeia/National Formulary (<http://www.usp.org>)
- British Pharmacopoeia (<http://www.pharmacopoeia.org.uk>)
- The European Pharmacopoeia (<http://www.phEur.org>)

Drug compendia

- Merck Index (<http://www.merck.com/pubs>)
- Physicians' Desk Reference (<http://pdrbookstore.com>)
- Martindale: the extra pharmacopoeia (<http://www.pharmapress.com>)
- DRUGDEX (<http://www.micromedex.com/products/drugdex>)
- Medicines Compendia (<http://emc.vhn.net>)
- Pharmaprojects (<http://www.pharmaprojects.co.uk>)

Formularies

- USP DI, Volume III, Approved Drug Products and Legal Requirements (<http://www.usp.org>)
- BNF (<http://www.bnf.org>)

SECONDARY SOURCES: INDEXING AND ABSTRACTING SERVICES

Journals are usually the most up-to-date form of primary and secondary scientific literature and the number of new biomedical journals has grown rapidly. Computerized abstracting and information databases are often the first port of call to gain access to the published journal literature on a particular drug topic. There has been a plethora of new drug information system products in recent years but perhaps the most useful, with an international outlook, are MEDLINE, EMBASE, IPA, CAPLUS, and BIOSIS Previews. These databases are traditionally classed as indexing and abstracting resources and, traditionally enough, started life as paper-based services, although it should be noted that one of the great advantages of their electronic versions is that it is possible with some of them to link directly to the full text of a journal article on screen.

MEDLINE

Produced by the National Library of Medicine in the United States, MEDLINE is the computerized form of Index Medicus, the Index to Dental Literature, and the International Nursing Index dating back to 1966. Over 4600 biomedical journals are indexed from more than 70 countries, although 52% of its current records are from U.S. journals and 75% are derived from English language publications. Updated weekly, 67% of the entries contain abstracts.

When searching for a drug in MEDLINE, it is best to use a generic name. The U.S. Adopted Names are preferred, as the brand name can only be searched for if it is in the title or abstract of the original article. However, since June 1980, the NLM has added other searchable fields to ease drug searching. It is now possible to search on CAS registry numbers, Enzyme Commission Numbers, and the substances of those numbers.

EMBASE

EMBASE is the electronic form of *Excerpta Medica*, from the publisher Elsevier Science. It contains indexed articles from more than 4000 biomedical journals from 119 countries, although again the English language dominates. EMBASE is stronger on European and Far Eastern literature than MEDLINE. Books were also included from 1975 to 1980. The database goes back to 1974 and is updated weekly.

The generic name, the standard being the WHO International Nonproprietary Name, is the first choice of the EMBASE indexers and for "combination preparations" the brand name is preferred. However, EMBASE

allows drugs to be indexed under numerous names, more so than MEDLINE, and even includes the name of the manufacturer if it is in the original article. EMBASE concentrates more on the pharmacological and toxicological aspects of the biomedical literature than MEDLINE.

IPA

International Pharmaceutical Abstracts, available electronically from 1970, from the American Society of Health-System Pharmacists, may only index around 800 journal titles but, as its name suggests, it specializes in pharmacy literature from around the world. A study by Bonnie Snow found that 12% of IPA's journals were not covered by MEDLINE, EMBASE, BIOSIS Previews, or Chemical Abstracts.^[1] IPA has also indexed ASHP meetings since 1988, meetings of the American Association of College Pharmacists and the American Pharmacy Association. All records have abstracts.

The preferred index name for a drug is its U.S. Adopted Name. If lab codes and chemical names appear in the same article, lab codes are preferred. When looking for an enzyme, try the CAS Registry Number before the EC Number.

For the literature on dosage forms, drug delivery, pharmacy practice, pharmacy law, cosmetics, pharmaceutical technology, and herbal medicines, IPA is one of the premier resources.

CAPLUS File

CAS, a division of the American Chemical Society, produces a large number of databases which cover a range of sciences; not only for chemistry, but also for physics, biology, and the applied sciences. CAS's CAPLUS, developed from Chemical Abstracts, is one of the largest indexing and abstracting databases for chemistry, going back to 1907 and covering over 8000 journals as well as conference proceedings, dissertations, books, and patents from 33 national patent offices. Patents make up 30% of the database. Electronic journals and Web preprints are also included. Updated daily, the literature has worldwide coverage, taking material from 130 countries and from 47 languages.

CAPLUS is particularly useful to do research for the first stages of drug development. However, it is not so useful for clinical practice. Inevitably, the best way to search for a substance is to use its CAS registry number. It is even possible to draw a chemical structure and conduct a search on it for post-1966 data. Generic and brand names are indexed for searching only if they are provided by the author in the original source.

BIOSIS Previews

From the U.S. BioSciences Information Service, BIOSIS indexes life sciences material from around 5500 journals, theses, conference proceedings, books, and organizational reports. Some U.S. patents were included from 1986 to 1989. The literature is from over 100 countries and from 57 languages. Once again, the English language dominates with 86% of the references being derived from English language sources. BIOSIS goes back to 1969 and is updated weekly. Author abstracts have been given for 55% of references since 1976.

The life sciences remit of BIOSIS means that it covers a wider range of scientific subjects than MEDLINE or EMBASE and has a focus on research rather than clinical practice. As a result, it is good for finding literature on early drug development.

When searching for a drug the U.S. Adopted Name is the first choice, but since 1998 it is also possible to search using CAS registry numbers. Note that it is only possible to search on the fields of brand names, Enzyme Commission Numbers and lab codes if they are given in the original literature source. The indexers at BioSciences Information Service will not add them to the database.

Other pharmaceutical and indexing services which have less of an international remit, but nevertheless have an important place in the drug information armoury include Pharm-line and RPS e-PIC.

Pharm-line

Around 100 English-language pharmacy and medical journals are indexed by pharmacists in UK NHS hospitals. The project is based at the Guy's and St. Thomas's Hospital Trust in London and involves the UK Drug Information Pharmacists' Group. The database, which goes back to 1978 and is updated weekly, is good for pharmacy practice and clinical pharmacy.

RPS e-PIC

Produced by the Royal Pharmaceutical Society of Great Britain e-PIC (electronic Pharmacy Information Coverage) consists of five databases which contain references selected from the major UK pharmacy practice and medical journals since 1992. The databases are e-PIC, which looks at pharmacy practice, New Products, Discontinued Products, Pharmaceuticals-Ceuted which covers pharmaceuticals, formulation and technology and Pharmacy History.

Criteria/Issues for Selecting an Indexing and Abstracting Service

Searching the secondary literature can be an expensive and time-consuming business, and the intensive marketing of some of the abstracting databases can make objective choice difficult. We have suggested further criteria that could be useful when choosing a database:

1. Subjects covered and the use of descriptors.
2. The fields that are searchable. What information is indexed? For example, can you specify a brand name search?
3. The type of material covered.
4. Geographical coverage.
5. The criteria for items being included.
6. Designated audience.
7. The standing of the service created—is it from a respected institution?
8. Size of the database—the total number of records and the number of journals considered.
9. The years covered.
10. The currency of the service—how often is it updated and what is the time delay between an item being published and it appearing in the database?
11. The inclusion of abstracts.
12. The user friendliness of the interface and the quality of the "Help" screens.
13. The ease of downloading and/or manipulating results.
14. Cost—not just for the database itself but for also for equipment and online costs, if applicable.

It is worth noting that not all of these criteria are linked to the database itself; they may relate to the supplier of the software operating the database. For example, MEDLINE can be purchased from many software vendors, including Ovid and Compact Cambridge. All vendors will provide you with a different user interface and will have varying prices. They will also vary in the timeliness of the latest material on the database, depending on when they update their products from the National Library of Medicine's MEDLINE source data. The NLM also provides its data for free via PubMed (<http://www.ncbi.nlm.nih.gov/PubMed>) and the NLM Gateway (<http://gateway.nlm.nih.gov>). As several studies have shown, there are overlaps in coverage between the main indexing and abstracting services, but enough differences to mean that searchers need to use more than one service to gain an accurate picture of the relevant literature.^[2,3]

PRIMARY SOURCES

Patent Information

Each country has its own laws for patents, which means it is important to remember that countries differ in the length of protection time given; the name used for the term “patent”; and even about what can be patented. In the United States, patents are sometimes known as “utility patents,” but note that some countries provide “utility models” which are similar to patents, but are not as inventive and which also have a shorter protection period. Utility patents are also called “petty patents” (or “Gebrauchsmustern” in German). In the UK, it is neither possible to patent a new plant or animal, nor a method of treatment of the human or animal body by surgery or therapy or a method of diagnosis. However, this is not the case in all countries; e.g., in the United States, plants can be patented.

Patent searching is a specialized field, but there are several useful options for the novice patent searcher. All patent offices will keep indexes of what they have and many of these will be computerized. Chemical Abstracts include patents. A free service on the Web is esp@cenet (<http://gb.espacenet.com>), which is provided by the European Patent organization. It contains over 30 million worldwide patents going back to 1920, although the past three years are the most comprehensive. For some of these patent applications you can obtain the full text, for others only abstracts or basic bibliographic details. The U.S. Patent and Trade Mark Office Database (<http://www.uspto.gov/patft/index.html>) gives the full text of patents issued since January 1 1976 and the full-page images of every U.S. patent issued since 1790. The UK Patent Status Information Service (<http://webdb4.patent.gov.uk/patents>) provides information on the status of a UK patent, e.g., it is possible to see if it is still in force, if you know the Publication or Application Number.

It is worth noting that there is an inevitable overlap between patent and journal literature, as researchers who are registering patents will often be publishing their work in article form throughout a project.^[4] One study found that 60% of British pharmaceutical patents had been written about in article form. But of course that still leaves 40% which were not, and in any case the information contained in patents often differs from that given in journal papers.

e-Journals

A growing number of printed journals provide their contents online. Sometimes, this is for free—e.g., the *Pharmaceutical Journal* (<http://www.pharmj.com>) of the Royal Pharmaceutical Society of Great Britain. But more often than not a subscription is needed. For details of other

online pharmacy journals try the Virtual Pharmacy Library, PharmWeb (more information on these is given below in the section *Internet Resources*), and the Free Medical Journals site (<http://www.freemedicaljournals.com>). Some journals will provide additional information online to their printed versions. *Nature's* Web site (<http://www.nature.com>) contains auxiliary data from authors, a link to a grant database and the opportunity to take part in online discussions.

Collections of e-journals, online and CD-ROM, can be purchased so that you can access your own personal “virtual” library from your desktop. One of the largest collections is that from the publisher Elsevier Science, which provides access to over 1000 of its journal titles at ScienceDirect.com. Other collections include the Wiley Interscience and the American Chemical Society. Obviously, many of the titles in these collections will not be directly related to the pharmaceutical sciences, so a careful examination of the journals included is recommended before making a purchasing decision. You may find it more economical to use “pay per view” rather than take out a subscription to the full text of a collection/title.

Electronic only journals were pioneered by American physicists, but now encompass all areas of science. To look at free e-only journals, try the Public Library of Science (<http://www.publiclibraryofscience.org>) and BioMedNet (<http://www.bmn.com>). Electronic journals have their advantages: ease of availability in that you no longer have to make a special visit to a Library; they do not take up shelf space, and you no longer need to spend money on binding and binding repairs. For libraries, they have the added advantage of making it easy to gather statistics on usage to help inform acquisition decision-making. However, there are issues/questions that warrant consideration before moving from print to electronic journal subscriptions, some of which are as follows: Identifying and locating electronic resources can take more time than print.^[5] Printed journals are still generally more portable and easier to browse. Continuing access: if you cancel a title, will you still be able to access the issues you paid for? Archiving: will the publisher maintain a permanent archive? (In the UK, at present, there is no legal requirement for electronic/digital material to be placed in a national depository.) Will the publisher be willing to transfer the data to a new medium if the existing technology proves to be transitory? (In the late 1980s, as we all moved away from microfiche, we were told that CDs would last forever, but we have since discovered that their average life-span is from 10 yr to 15 yr.) Will the electronic edition of a printed journal be available before or after the print issue? Also, be sure to read the license conditions to check for any restrictive practices: for example, can you download an article rather than print it out?

INTERNET RESOURCES

The Internet, and in particular the World Wide Web, has brought about a huge change to the communication of drug information. Not only has it dramatically increased the amount of information (it has been estimated that the Web contains approximately 800 million pages of information^[6] and is doubling in size every year^[7]), but it has also enabled the lay person to easily access what in the past would have been “professional only” data. Governments, companies, societies, charities, educational establishments, and individuals are all contributing. It is not just the amount of information that can make the Internet difficult to search, it is also the difficulty in distinguishing between quality material and dubious material that could be downright dangerous. One survey looking at information on Ewing’s sarcoma found that 40% of web pages sampled were from nonreviewed resources and, of these, 6% gave incorrect information.^[8] There are many more such examples.^[9] Of course, it is not just drug information that can be obtained on the Internet, but also the drugs themselves. However, one must keep the dangers of the Internet in perspective.^[10] There is a great deal of extremely useful information available, and one should remember that the medium of print can also be abused.^[11]

If you need to search the Internet for an unknown site, a good place to start is a pharmacy specific “gateway.” This is a Web site which indexes relevant pages. The Argus Clearinghouse (<http://www.clearinghouse.net>) reviews these gateways (which are sometimes referred to as “virtual libraries” or “internet portals”). Started in 1994, PharmWeb (<http://www.pharmweb.net>) was one of the first gateways for pharmacy. It indexes sources from across the globe including governments, companies, societies, and pharmacy schools. The U.S. based Virtual Library: pharmacy section (<http://www.pharmacy.org>) also looks worldwide, but does have a U.S. bias, e.g., the UK’s National Health Service is not listed. PharmiWeb (<http://www.pharmiweb.com>) is designed for UK pharmaceutical industry and provides information on individual companies, employment vacancies, and news. InPharm.com (<http://www.inpharm.com>) is also aimed at industry, in that it creates web sites for companies to encourage commercial exploitation of the Internet, but it also lists web sites by topic (e.g., new drugs for stroke), and includes directories of those involved in medical communications, along with industry news and vacancies. A site designed by the London and South Eastern Drug Information Service, aimed at health professionals, is called DrugInfoZone (<http://www.druginfozone.org>). It contains a new section: the latest issues of current awareness bulletins and monthly bibliographic citations from the PharmLine database. Governments are

increasingly recognizing the need to steer the rapidly expanding number of Internet users towards quality health sites, and to utilize this source of information and communication to the benefit of both health providers and consumers. The U.S. Healthfinder (<http://www.healthfinder.gov>) does not just link to government information; it also lists companies, societies, charities, and academic institutions. The Electronic Library for Health (<http://www.nelh.nhs.uk>) has been designed by the UK government for professionals and the layperson, while NHS Direct (<http://www.nhsdirect.nhs.uk>) provides patients with information on symptoms, conditions, illness, and disease. The U.S. Food and Drug Administration has its own web site (<http://www.fda.gov>) but you can also access FDA information on new drugs and recalls at Intellihealth (<http://www.intelihealth.com>) a site jointly developed by the Harvard Medical School, the University of Pennsylvania and Aetna US Healthcare. Drug information can be searched by generic, brand name, or condition being treated. Although designed for the layperson there is a “professional network” area. Another drug database created for patients and searchable by generic and trade name is MedMaster (<http://www.safemedication.com/about/medmaster.cfm>) from the American Society of Health-System Pharmacists. This has been developed from the ASHP’s *Medication Teaching Manual: The Guide to Patient Drug Information*.

For a list of pharmacy email services, try PharmWeb or the other pharmacy specific gateways discussed earlier.

Once again, much time and energy can be expended on “surfing the net” in the hope of finding relevant, good quality Internet sites providing required drug information. Thus, we have suggested the following guidelines in the hope that they will prove useful.

Criteria/issues for selecting internet resources:

1. Provider/publisher credentials: Are they reputable? A well designed and credible resource will provide an “about us” section, with contact details, and there may also be a site logo. Do you recognize the provider? The URL will also give you a hint as to the origins of an organization, e.g., .ac.uk for a British academic institution and .edu for a U.S. educational organization. If any funding sources are listed, would these detrimentally affect the information included?
2. Geographical origin: The “about us” section or the URL should help. All countries, apart from the United States, have a country code for their URLs, although increasingly the domain .com is being used worldwide without any reference to the country of origin. There is also the problem that anyone is free to register a co.uk domain. However, it is another piece of evidence to take into account.

3. Author credentials: Do you recognize the author and/or the organization from which they originate? If you do not, it is worth doing a search on a relevant quality indexing and abstracting service to discover if they have published on the same topic in a reputable journal.
4. Does the author provide references to back up any statements?
5. Currency: Does the site provide a date for when it was last updated?
6. Criteria for information being included. Check the "about us" and "help" sections for this information.
7. Designated audience: If the site is one you want to suggest to your patients, remember it is helpful and a good practice for the site to state that users should visit a health professional if they have any concerns.
8. Awards: Obviously, if a site has won a reputable award it is a positive indication, but make sure you know the credentials of the award. Reputable awards include those from the Health on the Net Foundation (<http://www.hon.ch>). Their Web site also acts as a gateway to quality medical information.
9. Security: It is worth checking to see if the site has a confidentiality policy, with mechanisms to back it up, if it collects sensitive personal information. Although, of course, one should always remember that no networked computer is totally secure.
10. Speed of access: This can be affected by the providers' and users' hardware, communication technology, and software. Location is also important—Internet sites are always quicker early in the morning providers' local time.
11. Ease of use.
12. Last but not least—price of use, if any.

CONCLUSION

There is little doubt that the already overwhelming quantity of drug information will continue to grow, causing severe problems to those desirous of keeping up-to-date in their field. Additionally, the impact of the Internet explosion has added a further layer of "information overload" to be reckoned with—it is now necessary to search out quality sources of information by the use of gateways and search engines. Indeed (and somewhat ironically) these have developed so quickly and to such an extent that we are now experiencing a difficulty in keeping abreast of the available gateways and portals, let alone the primary information on any topic. New products and packaged services aimed at helping users find drug information are regularly advertised and launched in all professional and scientific fora. Thus, it will become increasingly important for the end user to

develop and hone the evaluative skills of critical appraisal to enable him or her to choose good quality and relevant sources of drug information. Finally, it is hoped that readers will remember that experienced drug information scientists and pharmaceutical librarians are there to help with the quest.

DRUG DELIVERY—VAGINAL ROUTE

Yie W. Chien

Kaohsiung Medical University, Kaohsiung, Taiwan

Chi H. Lee

The University of Missouri-Kansas City, Kansas City, Missouri, U.S.A.

INTRODUCTION

Vaginal dosage forms have been developed and used clinically for many years in local therapy and the systemic delivery of systemically effective drugs. Pharmaceutical dosage forms available for intravaginal delivery consist primarily of those used to treat a specific gynecological condition. A small survey conducted to evaluate the preferences of females with regards to the use of intravaginal medications showed a positive market outlook for this mode of delivery (1). Products available include vaginal contraceptives, antifungals, antimicrobials, cleansers, deodorants, and lubricants. These products are formulated as tablets, capsules, creams, suppositories, foams, films, solutions, ointments, and gels. Currently, numerous prescription and over-the-counter (OTC) medications intended only for local activity in the vagina are available.

Recently, the vagina's absorption capacity has been recognized, which suggests that the vagina could provide a potential route for systemic drug delivery with a direct entry into the blood stream (Fig. 1) with the possibility of bypassing the hepatic-gastrointestinal (GI) metabolism. Several pharmacologically active compounds, that are metabolized extensively when taken orally, such as progesterone and estrogen, have been delivered intravaginally for achieving their systemic activity. Use of the vaginal route as a novel site for drug delivery has recently received greater attention, particularly with the new focus on the therapeutic agents that are subject to an extensive hepatic "first-pass" elimination, such as therapeutic proteins and peptides.

This article describes the physiology of the human vagina, its characteristics of absorption, and its permeability. The reader will also be familiarized with current research trends in vaginal delivery and absorption of drugs.

THE HUMAN VAGINA

General Anatomy

The vagina is a canal extending from the vulva to the cervix (Fig. 1). Extensive investigations on its morphology and anatomy have been compiled (2). Physiologically, the vagina serves a few functions, acting primarily as a conduit for the passage of seminal fluid, an excretory duct for menstrual discharge, and as the lower part of the birth canal (3). The anterior portion of the vagina in an adult averages 6–7 cm in length, while the posterior wall is approximately 7.5–8.5 cm.

The vagina is characterized by an exceptional elasticity, having the greatest resiliency at parturition. Along the length of the vagina, a layer of relatively thick connective tissue is located between the anterior vaginal wall and the urinary tract as well as between the posterior vaginal wall and the intestinal canal. The vaginal wall itself consists of three layers: The epithelial layer, the muscular coat, and the tunica adventitia. The epithelial layer is made up of an epithelial lamina and a lamina propria. It is a noncornified, stratified squamous epithelium that is subject to changes with aging. The epithelium atrophies from birth to puberty, at which time hormonal activity increases the thickness and resistance of this layer. In the subepithelial layer, there rests a network of elastic fibers around the lamina propria and collagenous fibers around the tunica adventitia, creating a connection to the muscular coat. Changes in the cytology of the vaginal epithelium occur with the cyclical stages in women. The epithelium is thickest in the proliferative stage, peaking at ovulation, and then diminishing with the secretory phase. The muscular coat of the vagina is composed of smooth muscle and elastic fibers. A spiral arrangement of these fibers provides support to withstand stretching without rupturing the vagina. The tunica adventitia is formed of loose connective tissue that is attached to the muscular coat. Fluctuations in

Fig. 1 Lateral view of the female pelvis showing the absorption route to the systemic circulation.

the volume of the vaginal lumen occur due to alterations in the tension of this layer. The vagina is encompassed by a vascular supply of arteries, veins, and lymph capillaries, as well as sensory and autonomous nerves.

Cellular structure

Histological studies of vaginal biopsies from healthy volunteers during follicular and luteal phases,

postmenopause, and following ovariectomy have been conducted to characterize the ultrastructure of the vaginal mucosa by electron microscope (4). The epithelium of the vaginal mucosa is found to have five different layers of cells: The basal, parabasal, intermediate, transitional, and superficial layers (Fig. 2). The cellular types that make up these various layers renew continuously as they are stimulated by hormonal action and intracellular communication. The basal cells are typically columnar or squamous in shape with microvilli present on the surface of the cell membrane. Parabasal cells are similar to the basal cells in size and structure, but have a greater formation of surface microvilli and interdigitations. Their polygonal shapes are formed by adapting to spaces left free from neighboring cells. The cells of the intermediate layer possess microvilli and are of the largest cell type. The transitional cells that follow show noticeable signs of involution and surface characteristics of diminishing and thinning microvilli and intracellular junctions (desmosomes). Superficial cells, as indicated by their nomenclature, are the cells of the outermost layer during the follicular phase of the cycle.

The vaginal epithelium contains a network of intercellular channels that continuously undergo development, reaching a maximum during the ovulatory and

Fig. 2 Cross-sectional view of the vaginal wall with magnification of the stratified epithelial layers. (Based on Ref. 6.)

luteal phases. The channels present in the transitional and superficial layers do not change with the cycle as do those in the basal, parabasal, and intermediate layers. These channels provide a supply of nutrients and transport metabolites to and from the layers of the epithelium. Since the vagina is absent of secretory glands, lubrication is provided via these channels. Interestingly, different substances have been shown to be rapidly absorbed through the vaginal mucosa and will be discussed later. Intercellular junctions, including desmosomes and tight junctions, have also been identified. Desmosomes are most prominent in the intermediate layer and progressively become less toward the superficial layer, which may play a role in the desquamation of vaginal cells.

Since the vaginal epithelium is affected by ovarian hormones, cyclical variations can occur (Fig. 3). Although less intense than the uterine modifications, changes include proliferation, differentiation, and desquamation. During the follicular phase, the time period between the end of menstruation and the day of ovulation, mitosis increasingly occurs in the cells of the basal and parabasal layers, creating an increase in the number of layers and the thickness of the epithelium. The desquamating layers increase until ovulation, after which the layers diminish and are sloughed away through the vaginal lumen. During the luteal phase, the period after ovulation, the transitional cells become superficial due to the absence of the normal superficial layer.

It has been found that the basal cells replicate continuously to provide a self-cleaning mechanism to the epithelial layer. Autoradiographic studies of cell proliferation were performed on normal human cervix and vagina (5). The turnover time, an indication of the time required for the replacement of the cell population, was determined from these studies. Results showed the basal layer to be relatively inactive with a turnover rate of 33 days, while active proliferation occurred in the parabasal layers with a turnover rate of 3 days. The intermediate and superficial layers were found to be inactive differentiating compartments.

Fluids and enzymes

Despite the paucity of glands, the vaginal epithelium is usually kept moist by a surface film. This film, known as vaginal fluid, consists of cervical mucus and exfoliated cells from the vagina itself. Transudation from the blood vessels through the intercellular channels to the lumen can also contribute to the chemical composition (4). The fluid can contain carbohydrates, amino acids, aliphatic acids, protein, and immunoglobulins (Igs) (6). Nonserum proteins in human vaginal secretions have recently been

Fig. 3 Profile of the gonadotropin and ovarian hormones during a normal menstrual cycle. The number of cell layers in the vaginal epithelium rises from 22 layers at approximately day 10 of the cycle to 45 layers at ovulation, and drops to 33 layers around day 20. (Based on Refs. 87 and 164.)

localized and analyzed (7, 8). Typically, the vaginal fluid in mature, healthy women has a pH in the range 4–5 (9). This acidic environment is produced by the presence of lactobacilli, which convert carbohydrates to lactic acid. The cervical mucus, a principal component of the vaginal fluid, is produced by glandular units within the cervical canal and has a pH in the range of 6.5–9. The cervical mucus changes in composition and physical characteristics with the menstrual cycle, facilitating sperm migration during ovulation. At the time of ovulation, the vaginal fluid increases in volume. This is due to the augmented amount of cervical secretions. The mucus produced at ovulation has increased spinnbarkeit (fibrosity), ferning (crystallization of the mucus when dried on a slide), pH, and mucin content (10). Additionally, a decrease in the viscosity, cellularity, and albumin concentration is noted.

The variety of enzymes found in the vagina is an important concern for the development of vaginal delivery systems, particularly with proteases and their effect on protein and peptide candidates (11). The outer cell layers of the vagina contain varying amounts of β -Glucuronidase, acid phosphatase, α -Naphthylesterase, diphosphopyridine nucleotide-diaphorase (DPND), phosphoamidase, and succinic dehydrogenase (9). Enzymatic activity has been shown in the basal cell layers as well, and these layers contain β -Glucuronidase, succinic dehydrogenase, DPND, acid phosphatase, and α -Naphthylesterase.

In addition to enzymes, the vaginal lumen is a nonsterile area inhabited by a variety of microorganisms, mainly *Lactobacillus*, *Bacteroides*, and *Staphylococcus epidermidis*, as well as potentially pathogenic aerobes (12). The existence of these microbes and their metabolites may also have a detrimental effect on the intravaginal stability of a vaginal drug delivery device.

Physiology and Dynamics

The unstimulated vagina anatomically consists of a luminal space that exists potentially rather than actually. However, in response to sexual excitement, some tension-induced anatomic variations occur. These anatomic variations may have effects on the long-term intravaginal delivery systems. These variations are reflected in the existence of four phases in a sexual response cycle as outlined by Masters and Johnson (13).

The first sign of physiological response (excitement phase) to stimulation is the production of a vaginal lubricating fluid. This appears on the vaginal mucosal surface within 10–30 sec after an effective stimulation. As sexual tension progresses, individual droplets of

transudation-like mucoid material appear scattered throughout the rugal folds of the vaginal lumen, coalescing to form a smooth coating over the entire vaginal mucosa surface. This transudative mucoid material results from the activation of a massive localized vasocongestive reaction and marked dilation of the venous plexus that encircles the entire vaginal lumen. This sweating phenomenon provides complete lubrication of the vagina. The inner two-thirds of the vaginal lumen lengthen and distend. As sexual tension mounts toward the plateau phase, the vaginal wall in this area expands involuntarily and then partially relaxes in an irregular, tensionless manner. The demand to expand gradually overcomes the tendency to relax. In addition to the expansive effect in the vaginal fornices, the cervix and corpus pull slowly backward and upward into the false pelvis position. This cervical elevation creates a “tenting effect” at the transcervical depth in the midvaginal plane. This phenomenon always occurs in a normal anteriorly positioned uterus (Fig. 4). The vagina of either nulliparous or multiparous women, regardless of prior degree of vaginal expansion or lengthening, increases substantially in length and transcervical width with sexual stimulation.

With attainment of the plateau phase level of sexual tension, a marked localized vasocongestive reaction develops in the outer one-third of the vaginal lumen. The

Fig. 4 Lateral view of the female pelvis showing the stimulated vagina. (Based on Ref. 13.)

entire area becomes grossly distended with venous blood, and its central lumen is reduced by at least a third as compared to the distention previously established in the excitement phase. The increase in the width and depth of the vaginal lumen is minimal. The production rate of vaginal lubricating fluid also gradually slows, particularly if this level of sexual tension has been experienced for an extended period of time.

During the orgasmic phase, the basic response of the inner vaginal lumen is essentially expansive rather than constrictive in character. On the other hand, the bulbar vasoconstriction at the orgasmic platform in the outer one-third of the vaginal lumen contracts strongly in a regularly recurring pattern. The intercontractile intervals lengthen in duration, and the intensity of the contractions progressively diminishes.

Along with the onset of the resolution phase, retrogressive changes develop first in the outer one-third of the vaginal lumen. The localized vasocongestion is dispersed rapidly, leading to an increase in the diameter of the central lumen of the outer one-third of the vagina. The previously expanded inner two-thirds of the vaginal lumen also gradually shrinks back to the original collapsed, unstimulated state. This shrinking process is an irregular, zonal-type relaxation of the lateral and posterior walls. The anterior wall and the cervix of the anteriorly positioned uterus descend rapidly toward the vaginal floor, leading to a quick resolution of the tenting effect created earlier during the excitement phase.

Menopause

The natural aging process results in significant changes in the vagina, including a decrease in vaginal size, loss of elasticity, loss of vascularity, and a thinning of the mucosa (14). The cytology of the vagina is variable and many aspects are addressed by Steger and Havez (14). The epithelium becomes markedly thinner and is often invaded with leukocytes. Areas can be completely denuded of an epithelial covering, exposing the subepithelial connective tissue. On the surface of the vagina, the numbers of exfoliating cells and microridges are greatly reduced. Creating the loss of elasticity, collagen replaces many of the elastic fibers in the lamina propria. Glycogen is very low or completely absent, contributing to the change in vaginal microbiology and pH. Vaginal secretions become scant and watery, and the pH increases from 4.5–5.5 to 7.0–7.4. Resistance to bacterial and fungal infections is reduced due to the lower population of acidophilic organisms (15). The enzymes present in the vagina also increase with the onset of menopause, including

β -Glucuronidase, acid phosphatase, and nonspecific esterases (14).

Unlike other tissues, the vagina is greatly affected by steroid replacement therapy. Estrogen replacement therapy is often used to treat menopausal symptoms. The postmenopausal state of the vaginal epithelium, with its thinner epithelium and increased permeability, is an important consideration in drug delivery. The minimization of epithelial fluctuation will result in less fluctuation in absorption, affecting both systemic and local drug deliveries.

VAGINAL ABSORPTION

Much has been written in the literature concerning vaginal absorption. The first experimental studies using animals dates back to 1918. At that time, the histological characteristic of the vaginal wall was known to exist in three simple layers: the connective tissue, muscular, and the mucosa, collectively resembling the skin without the stratum corneum. Originally, the vagina was regarded as an organ impermeable to exogenous agents. Reports began to surface that indicated vaginal absorption of foreign materials as the cause of toxicity and even death in several cases. Using dogs and cats, vaginal absorptions of large varieties of compounds, including alkaloids, inorganic salts, esters, and antiseptics, were demonstrated (16). Later work showed the vaginal absorption of compounds such as hydrocyanic acid, pilocarpine, atropine, and insulin in dogs and cats (17). Using rabbits, cats, and dogs, the vaginal absorption of quinine bisulfate and oxyquinoline sulfate was set forth, intending to emphasize the care and consideration required of physicians with regards to the local applications of medication to the vaginal mucosa (18). A unidirectional transmission of agents was proposed to occur from the vagina to the blood, with no transmission in the reverse direction (19, 20).

An extensive review of the literature documented the absorption of carbohydrates, fats, and proteins (21, 21). Glucose was absorbed and rapidly oxidized. One of the first proteins demonstrated to be absorbed vaginally was peanut protein (23). The vaginal permeation of spermatozoa and bacterial antigens also has been shown (22). Bacterial antigens play an important role in triggering the local immunological mechanisms involved in protecting the area against infection. Other classes of compounds include steroids (e.g., estrogens, progesterone, and testosterone), prostaglandins, antimicrobials, nonoxonyl-9, and methadone. The vaginal delivery of estrogen and

Fig. 5 Rabbit plasma concentration profiles of norethindrone following the intravenous administration of a single dose (solution). Also shown is the intravaginal absorption of ethynodiol diacetate from a solution dose and from a vaginal delivery device. (Based on Ref. 37.)

progesterone has been well documented over the years and used clinically in dosage forms, such as vaginal creams and suppositories.

Vaginal absorption of drugs is dependent upon such physicochemical properties as molecular weight, lipophilicity, ionization, molecular size, chemical nature, and local action, as well as the thickness of the vaginal wall as affected by the ovarian cycle or pregnancy (21). Other factors include changes in the vaginal epithelium and pH with menopause. Prior to absorption, drugs must be in solution. The fluid present in the vagina can

Fig. 6 Schematic of the vaginal membrane as a transport barrier. (Based on Ref. 25.)

help to dissolve drugs, but the cervical mucus secretion also can present a barrier and remove a drug from the site when abundant (11). Dosage forms can undergo different absorption due to the differing dissolution patterns in vaginal fluid. Products such as creams, inserts, and tablets remain for different periods of time in the vagina. A comparison of vaginal inserts versus creams showed that creams have a longer contact time in the vagina (24).

Permeability

Transport across the vaginal membrane can occur by three primary pathways: the transcellular route, by which diffusion occurs through the cell due to a concentration gradient; the intercellular route, where diffusion occurs through spacing between cells; or by a vesicular or receptor-mediated transport (11, 25). Vaginal permeation studies have been conducted using the rabbit as an animal model (26, 27). The female rabbit does not exhibit an estrus cycle, so its vaginal tissues show constancy in the histological, biochemical, and physiological properties not ordinarily seen with most other mammals (28). The lack of a sexual cycle is, therefore, expected to produce a minimal variability in the permeability of the vaginal membrane, making the measurements of vaginal drug permeation more controllable and accessible (26, 27, 29).

The vaginal mucosa permeability of the doe rabbit has been examined by continuous perfusion of straight-chain alkanols and alkanolic acids (26, 27). Similar to the vaginal absorption of ethynodiol diacetate (Fig. 5), the vaginal uptake of both alkanols and alkanolic acids also follows a first-order rate process and is dependent on the drug concentration in the vaginal fluid. The results agree well with a physical model that has a hydrodynamic diffusion layer in series with the mucosal membrane, that consists of two parallel pathways: a lipoidal pathway and an aqueous "pore" pathway (Fig. 6). Immediately behind the mucosa (serosal side) a perfect sink is maintained by hemoperfusion.

The apparent permeability coefficient P_{app} for vaginal membrane permeation is defined by

$$P_{app} = \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_v}} \quad (1)$$

or

$$P_{app} = \frac{1}{\frac{1}{P_{aq}} + \frac{1}{P_p + P_l}} \quad (2)$$

since

$$P_v = P_p + P_l \quad (3)$$

where P_{aq} , P_v , P_p and P_l are the permeability coefficients of the aqueous diffusion layer, the vaginal membrane, the aqueous pore pathway, and the lipoidal pathway, respectively.

The vaginal permeation kinetics of a series of straight-chain alkanols was investigated (26). Using methanol as a reference permeant, a normalized permeability coefficient: $P_{app}(alc/MeOH)$ was determined for each of the alkanols. The normalized permeability coefficient was observed to increase in value as the alkyl chain length of the alkanols increased (Table 1). The increased permeability can be attributed to the increase in the permeability coefficient for the lipoidal pathway P_l (Eq. 2). It is estimated that for straight-chain aliphatic alcohol the P_l value increases by 2.5 for the addition of each methylene (CH_2) group (26). On the other hand, the P_l value increases by 3.5 for the series of straight-chain alkanolic acids (27).

For the vaginal absorption of ionizable compounds, such as the homologous series of n -alkanoic acids, the apparent permeability coefficient P_{app} becomes pH-dependent and is defined by Eq. 4:

$$P_{app}(n, pH) = \frac{1}{P_{aq}(n)} + \frac{1}{\frac{[H]}{K_a + [H]} P_l^0 10^n \pi + P_p} \quad (4)$$

where n is the number of methylene (CH_2) groups in the alkyl chain; $[H]$ is the concentration of protons; K_a is the dissociation constant of the acid; P_l is the permeability coefficient of the lipoidal pathway for the hypothetical acid with zero carbon atom ($n = 0$); and π is the methylene

Table 1 Effect of alkyl chain length on the normalized permeability coefficients of straight-chain alkanols^a

Alkanol	$CH_3(CH_2)_nOH$	$P_{app}(Alkanol/MeOH)^b$
Methanol	$n = 0$	1.00
Propanol	$n = 2$	1.11
Butanol	$n = 3$	1.13
Pentanol	$n = 4$	1.20
Hexanol	$n = 5$	1.48
Heptanol	$n = 6$	1.91
Octanol	$n = 7$	2.15

^aBased on data from Ref. 26.

^bNormalized permeability coefficient = $P_{app}(alcohol)/P_{app}(methanol)$. Mean value from three rabbits at pH 6.0 and 37°C.

Table 2 Effect of alkyl chain length and pH on the normalized permeability coefficients of straight-chain alkanolic acids

Acids	$P_{app}(Acid/MeOH)^a$		
	pH 3	pH 6	pH 8
Acetic	1.22	0.73	0.25
Butyric	1.62	1.94	0.34
Hexanoic	1.89	2.06	0.81
Octanoic	1.74	2.49	1.24
Decanoic	—	—	1.26

(Based on data from Ref. 30).

group incremental constant, that is, 3.5 for straight-chain alkanolic acids.

As illustrated earlier in the homologous series of n -alkanols, the normalized permeability coefficient of n -alkanoic acids also shows a dependence on alkyl chain length (Table 2). In addition, the straight-chain alkanolic acids demonstrate a pH-dependence in their normalized permeability coefficients (27). It should be pointed out that the rabbit's vaginal secretion has an effective pK_a value of 6.3 ± 0.1 . However, the rate of vaginal secretion is relatively small, which leads to a surface pH of around 2.0–2.1 (30). This acid surface pH affects the extent of dissociation of n -alkanoic acids and thus the magnitudes of P_l and P_{app} (Eq. 3).

The vaginal uptake of steroids has also been studied and follows a first-order rate process as well (31). The normalized permeability coefficient of steroids appears to be dependent upon steroidal structure (Table 3). The permeability coefficient across the vaginal membrane (P_v) also shows the same trend of structure dependence; the lipophilic steroids (progesterone and estrone) were better absorbed than the more polar steroids

Table 3 Vaginal permeation parameters of representative steroids

Steroids	P_{app}^a	$P_v \times 10^4$ (cm/s)	$P_{aq} \times 10^4$ (cm/s)
Estrone	1.00	7.60	2.81
Progesterone	0.93	6.10	2.80
Testosterone	0.29	0.75	2.76
Hydrocortisone	0.23	0.58	2.79

^aNormalized permeability coefficient = $P_{app}(steroid)/P_{app}(methanol)$. (Based on data from Ref. 31.)

(hydrocortisone and testosterone). However, the P_{aq} values, the permeability coefficient across the hydrodynamic diffusion layer, are very much the same among the four steroids (Table 3). For drugs with high P_v values, such as progesterone and estrone ($6.1\text{--}7.6 \times 10^{-4}$ cm/s), vaginal absorption is mainly controlled by their permeability across the hydrodynamic diffusion layer on the surface of the vaginal mucosa ($P_v > P_{aq}$). Conversely, for drugs with low P_v values, such as testosterone and hydrocortisone ($5.8\text{--}7.5 \times 10^{-5}$ cm/s), vaginal uptake is determined predominantly by their molecular permeation through the vaginal membrane ($P_v \gg P_{aq}$) (32). A linear relationship between the vaginal permeability and a series of progestins and their lipophilicities have been shown in vitro using rabbit epithelium (33).

The apparent permeability coefficient P_{app} is related to the first-order rate constant for the disappearance of drug from vaginal lumen (k_v) as follows:

$$P_{app} = k_v \frac{V_v}{S_v} \quad (5)$$

where V_v is the volume of vaginal fluid and S_v is the geometric surface area of the vaginal lumen.

Additional permeability studies have been conducted in rabbits by the measurement of electrical conductance and flux measurements of a hydrophilic fluorescent probe 6-Carboxyfluorescein (34). Membrane permeation selectivity was indicated by KCl diffusion potential or charge-discriminating ability. The fluorescein probe is known to permeate via the paracellular route. The permeation of the 6-carboxyfluorescein was found to be in the order of intestine \approx nasal \geq bronchia \geq tracheal $>$ vaginal \geq rectal $>$ corneal $>$ buccal $>$ skin. The permeation selectivity was found to be negative; in other words, the K^+ ion was more permeable than the Cl^- . With all the tissue types evaluated, the permeation selectivity was found to be similar. Using low-molecular-weight polyvinyl alcohol, the molecular weight cutoff of the vaginal epithelium of rats was found to be greater than other assessable surfaces, such as the GI tract (35). Permeability trends have been evaluated using the spermicide, nonoxynol-9 (36). A linear correlation was observed between permeability and partitioning of nonoxynol-9 oligomers using lamb vaginal mucosa, suggesting the importance of the lipoidal pathway for this particular agent.

Pharmacokinetics

If the absorption, distribution, and elimination of a drug molecule after its release from a vaginal drug delivery device in the vaginal lumen follow the pharmacokinetic

sequences,

then the instantaneous rate of change in drug concentration in the central compartment can be expressed by Eq. 6:

$$\frac{d(C_c)}{dt} = k_a C_v + k_{tc} C_t - (k_{ct} + k_e) C_c \quad (6)$$

where k_a , k_e , k_{cy} , and k_{tc} are the rate constants for absorption, elimination, and central compartment/tissue compartment exchange, respectively, and C_a , C_c , and C_t are the drug concentrations in the tissue fluid surrounding the vaginal device, in the central compartment and in the tissue compartment, respectively.

The vaginal absorption of drug following its release from vaginal drug delivery devices may alternatively be described by a simplified one-compartment open model with first-order drug absorption (Fig. 5) (37). Using this simplified model, Eq. 6 is reduced to Eq. 7:

$$\frac{d(C_c)}{dt} = k_a C_v - k_e C_B \quad (7)$$

where C_v and C_B are the drug concentrations in the vagina and in the body (including blood, tissues, and related compartments with fast drug exchange rates), respectively.

At steady state (Fig. 7), the change in the body concentration of the drug is relatively small, $d(C_B)/dt \approx 0$. For example, the body concentration of norethindrone (C_B), the major metabolite of ethynodiol diacetate (Q), is then related to the amount of (Q) released at time t as shown by Eq. 8:

$$C_B = \frac{k_a \Sigma R_{2v}}{2k_e} \left(\frac{Q}{t} \right)_v \quad (8)$$

where ΣR_v is the total diffusional resistance across the vaginal wall. Eq. 7 suggests that the norethindrone concentration (C_B) in the body of each test animal should be directly proportional to the amount of Q released from the vaginal device, $(Q/t)_v$, for a given duration of intravaginal residence. From the slope of the C_B versus $(Q/t)_v$ plots and the values of k_a and k_e from the vaginal absorption studies of the same drug from a solution, the

Fig. 7 Plasma profile of norethindrone following the intravaginal insertion of ethynodiol diacetate-releasing vaginal devices in rabbits for 56 days and after device removal. (Based on Ref. 37.)

magnitude of R_v , the total diffusional resistance for the vaginal permeation of the drug, can be estimated.

Physiological Factors Affecting Drug Delivery through Vaginal Mucosa

Mucus: Compositions, characteristics, and roles

The vaginal mucosa, to which a bioadhesive drug delivery system is expected to come into contact when inserted intravaginally, consists of an epithelium having its surface coated with a layer of mucus. The mucus is a heterogeneous secretion and provides a protective and lubricating functions to the epithelium. In a normal woman, the mucus is produced by the cervix at the rate of 20–60 mg/day. During the midcycle, the rate increases to 700 mg/day (38) and the mucus becomes a less viscous and microstructurally more expanded in texture, which facilitates the penetration of sperm (39).

To understand the nature of mucus, it is necessary to understand the structure of glycoprotein, the principal biochemical component of the mucus subunit (40, 41). Glycoprotein, which has a molecular weight of 320–4500 Da, is bound to other subunits through disulfide

bonds and probably interacts with other subunits through ionic bonds and entanglements, especially with sialic acids located at the terminal ends of the oligosaccharide chain (42). In addition to glycoproteins, the cervical mucus also contains a wide range of substances, including plasma proteins, enzymes, amino acids, cholesterol, lipids, and inorganic ions, with concentrations known to fluctuate during the cycle (43). It has been proposed that entanglement of the macromolecules with the specific lectin-like regions contributes to the properties of the cervical mucus (44, 45). The relationship between the intrinsic viscosity and the molecular weight of the whole mucins and their subunits and T-Domains suggests that they are flexible linear macromolecules behaving like a stiff random coil (46).

The hostility of the thickened cervical mucus to sperm penetration has been used as a means to achieve contraception, and low-dose oral contraceptives depend largely on this condition for their effectiveness in fertility control (47, 48). Sequential oral contraceptives do not affect mucus and like estrogen, may even increase sperm penetration.

The change of viscosity in the cervical mucus

Alterations in the biochemical properties of mucus are known to be responsible for changes in rheological behavior and receptivity of mucus to various exogenous compounds (49). The liquefaction can be regulated by mechanical disruption, systemic carrier dilution, or chemicals, such as mucolytic agents. The effect of the alterations in the physical and physiological properties of cervical mucus on the change in drug permeability through the cervical mucosa was studied (50). Since marked changes occur in the plasma membrane during epididymal maturation and capacitation, analysis of the nature of compounds at biochemical level was important to understand the changes in permeation rate in response to the viscosity of mucus (51). The increased ionic strength and consistency of the periovulatory mucus offers better permeability to exogenous compound, and increased charge favors a higher degree of hydration (52).

The viscosity of mucus is affected by binding between calcium and the mucus, which probably arises from an ionic interaction with the sialic acid in the mucin (44). These variations are indicated by a change in the pH, viscoelastic properties, water, and protein content of cervical mucus (53). Calcium is needed to establish an intercellular contact and the assembly of tight junction in the cervical epithelium (54). Changes in extracellular calcium affect the permeability of tight junctions and play a role in regulating the production of cervical mucus (55). Prostaglandin concentrations in the cervix affect the

viscosity of cervical mucus, which in turn affects the cervical softening (56). The effect of dithiothreitol (DTT) on the viscosity was also reported (57). Thus, the physical and physiological properties of cervical mucus may reflect alterations in the macromolecular composition or concentration of its components on exposure to exogenous substrates or hormone replacement therapy (58). As an example, administration of mestranol (or ethinyl estradiol), in combination with norethisterone or its acetate was known to strongly affect the biophysical properties of the cervical mucus and sperm migration (59).

The change in protein composition in cervical mucus

Human cervical mucus contains 1–3% proteins, in which the major soluble proteins are albumin and gamma globulin (60). The effects of various agents on the protein composition were studied (61). When a purified glycoprotein was treated with various proteolytic enzymes, which degraded (the purified) glycoprotein, the charge of cervical mucus increased to confer a rigidity by the mutual repulsion of negative charges and strengthen the coherence and consistency of the secretion (62). It appears that the menstrual cyclic changes in mucus viscoelasticity in an individual can be accounted for by the changes in mucin concentration (63). This appears to result from a decrease in the amount of proteins in both the follicular and the luteal phases, but an increase in the ovulatory phase (64). In addition, mucus compositional differences may occur among individuals, as indicated by the different correlations seen in the viscoelasticity and the mucin concentration (65).

The effect of the combination of nonoxynol-9 and EDTA was studied and showed that spermicidal activity was significantly enhanced (48). The observations may be due to a partial removal of calcium, on addition of chelating EDTA, which may have caused a decrease in the dephosphorylation of regulatory proteins mediated by calcium, and further caused a change in the total amount of protein and its composition in the cervical mucus. The nature of mucus components, especially proteins and enzymes, need to be studied further to fully elucidate the mechanism by which cervical mucus regulates the permeation rate of exogenous compounds. A change in the protein composition is expected to affect enzyme activity in the cervical mucus and further affect the stability and permeation rate of a drug delivered by a vaginal drug delivery device (66).

Cyclic variability

As mentioned previously, the rabbit appears to be an ideal animal model for studying vaginal mucosa permeation due to the absence of an estrus cycle.

Unfortunately, the doe rabbit may not be a suitable animal model for studying long-term vaginal absorption because it lacks the typical cyclic variations observed in the human vaginal tract associated with the rhythmic pattern of hormones during a menstrual cycle. In the human female, the cyclic secretion of estrogenic hormones in the ovarian cycle induces variation in the histology, biochemistry, and physiology of vaginal tissues. It is, therefore, reasonable to expect that the vaginal mucosa undergoes a corresponding cyclic variation in its membrane permeability.

The macaque rhesus monkey has an ovarian cycle of approximately 28 days, as does the human female, and it also exhibits an estrus pattern very similar to the menstrual pattern of the human female. It is widely believed by researchers in the fertility field that rhesus monkeys and humans have comparable anatomy and physiology, as well as similar reproductive functions (67). Therefore, the female rhesus monkey is a superior animal model for studying the vaginal absorption of various drugs from a drug delivery system designed for use in human females.

The effect of the estrus cycle on the permeability of the vaginal mucosa has been demonstrated in the vaginal absorption of a small molecule, like methanol, which has a vaginal membrane-controlled permeation, and a larger molecule, such as *n*-octanol, with vaginal permeation controlled by the hydrodynamic diffusion layer (Fig. 8). Further studies that used intact and ovariectomized monkeys could not establish any systematic relationship between the menstrual cycle and vaginal membrane permeability (68). Conflicting observations were also reported in the vaginal absorption of penicillin in humans (69, 70) as well as in rats (71, 72).

The vaginal permeability of a cycling monkey during the period immediately following menstruation is lower than that of a noncyclic rabbit (Fig. 9). The difference in vaginal permeability between rhesus monkeys and rabbits is greater for hydrophilic molecules, such as the short-chain alkanols (e.g., methanol), whose vaginal permeability is controlled by vaginal membrane permeation. The difference lessens as the alkyl chain length of alkanols increases, since molecular lipophilicity increases at the expense of hydrophilicity. At ovulation, the monkey's vaginal permeability is several-fold lower than that of the noncyclic rabbit (31).

The cyclic variation in vaginal drug permeability observed in rhesus monkeys in association with the rhythmic pattern of the sexual cycle suggests that the vaginal absorption data generated in the rhesus monkeys may be more reflective of what will occur in humans. The rhesus monkey is, therefore, a good animal model for the research and development of intravaginal delivery devices.

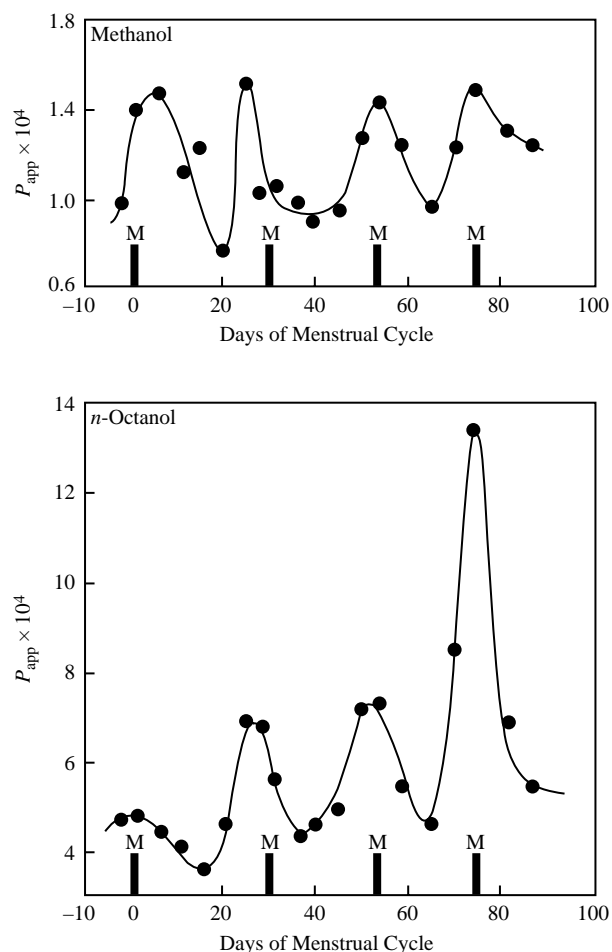

Fig. 8 Cyclic variation in the apparent permeability coefficient, P_{app} , of methanol and *n*-octanol in the female rhesus monkey in response to its estrus cycle. The bars indicate the time of observed menstruation. (Based on Ref. 31.)

TYPES OF VAGINAL DRUG DELIVERY SYSTEMS

Human Applications

Several publications have examined the many types of vaginal delivery systems already marketed or under development (73, 74). In the development of vaginal dosage forms, the following considerations should be addressed (73):

- Maintenance of an optimal pH for vaginal epithelium
- Ease of application
- Even distribution of drug
- Retention in the vagina
- Compatibility with coadministered medicines

Fig. 9 Comparison of apparent permeability coefficients, P_{app} , for the vaginal absorption of straight-chain alkanols in noncyclic rabbits and cyclic rhesus monkeys. (Based on Refs. 16 and 165.)

In addition, offensive odors, staining, tissue irritation, or pain during sexual intercourse are undesirable. With regard to systemic delivery, one key advantage of intravaginal administration is avoidance of the presystemic elimination associated with oral dosage forms. The perineum venous plexus, which drains the vaginal tissue and rectum, flows into the pudenda vein and ultimately into the vena cava, which circumnavigates the liver on first-pass. This is in marked contrast to GI blood circulation that drains into the portal vein and passes directly through the liver before entering the systemic circulation. The vaginal route is preferable for drug entities associated with GI irritation and for the localized treatment of vaginal disorders that require minimal systemic absorption.

Creams, foams, and jellies

Many OTC vaginal products are available in these types of preparations. Common products include contraceptive creams, foams, gels, suppositories, sponges, and films, that contain an active spermicidal agent, like nonoxynol-9 or octoxynol. Vaginal preps are a recent FDA-approved OTC treatment for yeast infections (75). For treatment of menopausal symptoms, estrogen products are available as vaginal creams. A relatively new product for postmenopausal women, Replens®, is available as a vaginal bioadhesive moisturizer. It has been shown to be as safe and effective as estrogen vaginal creams in increasing vaginal moisture, fluid volume, elasticity, and returning the pH to the premenopausal state (76). Low pH lactate gels have been dispensed for the treatment of bacterial vaginosis. Application of these gels leads to a

disappearance of abnormal discharge and malodor, restores normal acidity, and facilitates recolonization with lactobacilli. Local treatment for vaginosis by the intravaginal delivery of antimicrobials may be preferred over an oral regimen, particularly during pregnancy (77).

When the efficacy of a vaginal ring, which delivers a continuous low dose of estradiol, was compared with a vaginal cream, both formulations were found to be equally effective and safe in the treatment of postmenopausal women with urogenital atrophy symptoms (53).

Vaginal rings

Vaginal rings provide a means of delivering a pharmacologically active agent to the systemic circulation at a controlled rate of release. The vaginal rings developed to date are primarily used for contraception and have been reviewed in the literature (74, 78). Compounds delivered include medroxyprogesterone acetate (MPA) (79–85), estradiol (53, 58, 86, 87), norgestrel (88, 89), levonorgestrel (90–94), combinations of progestins and estradiol (95), and combinations of progesterone and estrogens (96–101). Another area of interest is in the controlled delivery of prostaglandin for cervical ripening and induction of labor or pregnancy termination (102).

An advantage of intravaginal controlled drug administration over conventional oral administration is best illustrated in Fig. 10. After oral ingestion, MPA, reaches a peak plasma drug concentration rapidly within 2 h and declines over the next 22 h. On the other hand, intravaginal controlled delivery of MPA from a vaginal ring attains a steady plasma plateau within 4 h, which is maintained throughout the course of treatment until removal of the ring. The continuous “infusion” of drugs through the vaginal mucosa can prevent the possibility of hepatic GI first-pass metabolism and inefficient therapeutic activity resulting from the alternatively surging and ebbing plasma drug levels that occur with the intermittent use of oral dosage forms (31). Vaginal rings have been shown to be safe and effective for the delivery of estradiol and have been found to be more comfortable than a pessary (103). Local estradiol delivery via vaginal ring, vaginal cream, or suppositories, was reported to alleviate urogenital estrogen deficiency symptoms in postmenopausal women (53, 58). In both cases, patients showed a strong preference for the vaginal ring over other vaginal dosage forms. Danazol, that was administered intravaginally also via the vaginal ring was found to be very effective in the treatment of pelvic endometriosis (104). Danazol was absorbed through the vaginal mucosa and reached the deeply infiltrating endometriosis via diffusion.

Vaginal rings are made of biocompatible silicone elastomers that consist of a drug-free core ring and a

Fig. 10 A) Serum concentrations of medroxyprogesterone acetate after a daily oral administration of a medroxyprogesterone acetate tablet (10 mg) taken by a healthy woman before breakfast for five consecutive days. B) Daily serum concentrations of medroxyprogesterone acetate in women wearing medicated silicone vaginal rings (2% medroxyprogesterone acetate) for 20 days. (Based on Ref. 53.)

drug-containing coat. Vaginal rings are inserted and positioned around the cervix. Those designed for contraception, are kept intravaginally for 21 days and removed for 7 days to allow menstrual flow. The vaginal ring was redesigned due to frequent bleeding irregularities. The new generation of sandwich-type vaginal rings contains a drug-dispersed silicone polymer matrix is coated by a nonmedicated silicone polymeric membrane. The design reduces the initial spike of drug release frequently observed in the first treatment cycle of vaginal rings for contraception. The effect of the overcoat on the release rate profile of d-norgestrel is demonstrated in Fig. 11, which shows that the addition of an overcoat minimizes or eliminates the burst release of drug and shifts the non-zero-order drug release profile to the constant zero-order release rate profile. The concept of intravaginal dual

Fig. 11 Comparative in vitro release rate profile of levonorgestrel from a vaginal ring containing a homogeneous dispersion of drug in a silicone-based polymer matrix (open circles) and from one containing an inert overcoat covering the drug reservoir layer (closed circles and squares). The effect of overcoat thickness h_m on the release rate of levonorgestrel is also shown. (Based on Ref. 25.)

administration of progestin and estrogen in combination was recently extended to the development of a combined contraceptive vaginal ring. This new design (Fig. 12) is constructed from two drug reservoir compartments; the major compartment consists of a 3-Keto-desogestrel loaded core, and the other, minor compartment consists of a core loaded with a combination of 3-Keto-desogestrel and ethinylestradiol, a synthetic estrogen. These drug

Fig. 12 Structural components of a contraceptive vaginal ring containing the combination of 3-keto-desogestrel and ethinylestradiol. (Based on Ref. 67.)

reservoir compartments are separated by two steroid-impermeable glass closures, as the partitions, and release the steroids at a fixed ratio through a rate limiting silicone membrane (98). Serum profiles of 3-Keto-desogestrel and ethinylestradiol from two prototype vaginal rings are shown in Fig. 13.

Veterinary Applications

Pessaries

Intravaginal drug delivery has been a useful tool in animal husbandry to control the estrus cycle of sheep and cattle. Synchronization of a herd estrus cycle eases the management strains on ranchers and farmers. Fluorogestone acetate, an effective ovulation inhibitor in the ewe, has been formulated into a vaginal pessary for sheep. The pessary is placed in the ewe for about 15 days. The pessary is removed and the sheep regain their estrus and ovulate within 2–4 days. This permits insemination of all sheep within a 2-day period and with a high success rate. Commercial delivery systems include Syncro–Mate vaginal pessary (S.D. Searle & Co.), Chronogest vaginal pessary (Intervet S.A.), and PRID vaginal insert for dairy cattle (Sanofi Animal Health Ltd.), which contains progesterone and estradiol benzoate. A MPA sponge has been used to evaluate the preovulatory gonadotropin surge in ewes (105).

Modified vaginal pessaries

The Syncro–Mate progestin-releasing vaginal pessary is fabricated by dispersing a progestin, such as fluorogestone acetate, in a pessary made of porous polyurethane sponge. The pessary can be readily inserted intravaginally and removed according to a predetermined schedule. The vaginal pessary has been redesigned with the aim of minimizing the loading dose, to overcome the matrix-type release and absorption profiles, and to improve systemic bioavailability. Work evaluating a cylindrical, drug-free polyurethane vaginal sponge coated by a laminate of fluorogestone-containing silicone matrix and a drug-free silicone coating membrane was conducted (106–108).

The system itself was modified and the release rates studied in vitro and in vivo. It was found that the drug-containing silicone layer needed to be in contact with the vaginal wall. A silicone coating did not result in adequate release rate. Also, as the surface area of the drug-containing silicone increased, the drug delivery rate increased. This effort has resulted in two new pessary designs (Fig. 14). Both types make use of the polyurethane sponge in the vaginal pessary as the mechanical support for vaginal insertion and retention, but

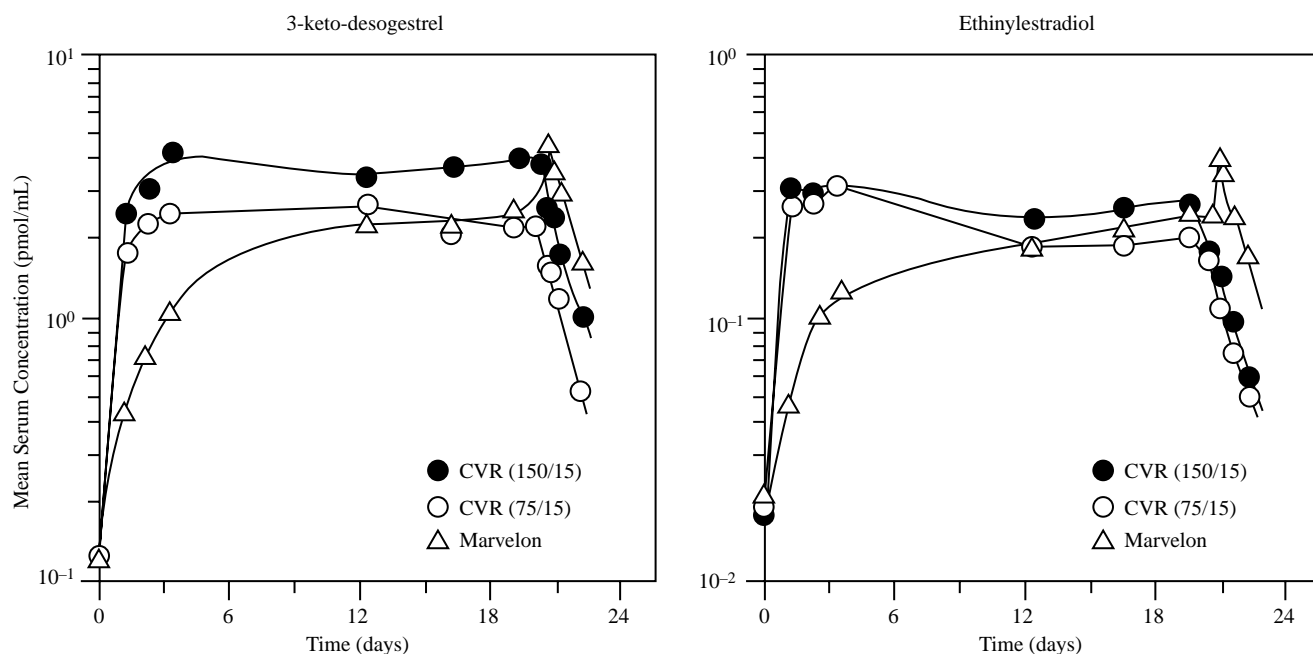

Fig. 13 Mean serum profiles of 3 keto-desogestrel and ethinylestradiol after a 21-day continuous intravaginal administration of two prototype combination contraceptive vaginal rings (CVR). The profiles from an oral combination tablet (Marvelon) is plotted for comparison. (Based on Ref. 67.)

the drug reservoir is relocated from the porous sponge matrix to a sheet-type rate-controlled silicone device that

Fig. 14 Comparison of newer progestin-releasing vaginal pessaries (Type I and II) with an older (Syncro-Mate) pessary design. (Based on Ref. 25.)

covers the circumferential surface of the sponge. The type I rate-controlled silicone device consists of a homogeneous dispersion of drug in a silicone polymer matrix. The type II drug-dispersing polymer matrix is sandwiched between two sheets of silicone polymer membrane to form a three layered laminate.

Potential Developments in the Future: Bioadhesives

Novel intravaginal delivery systems include those that employ bioadhesive materials. The bioadhesive properties of compounds such as hydrogels may provide a controlled delivery system with a prolonged residence and intimate contact in the vagina. Many hydrophilic polymers and hydrogels have been used in vaginal products. These include starch, collagen, proteins, gelatin, and cellulose derivatives (hydroxypropyl methylcellulose, hydroxypropyl cellulose, and sodium carboxymethylcellulose) (77). Two synthetic hydrogels that have been reported in applications for vaginal drug delivery are poly(ethylene oxide) and poly(acrylic acid). Bioadhesion is thought to involve an initial interaction of the hydrogel with the mucosal surface, which requires a matching of the polarity between the tissue surface and the polymer surface (109), and subsequently, an interpenetration of the mucosal surface by the polymer chains of the hydrogel.

A review of vaginal bioadhesive formulations indicates that bioadhesive tablets have been used for localized treatment of diseases in the vaginal tissue (77, 109). For example, Bleomycin, an antitumor agent, was incorporated into a flat-faced disk fabricated from a combination of hydroxypropyl cellulose and poly(acrylic acid) (Carbopol 934) (110). The tablet was designed to release Bleomycin at a slow rate to minimize irritation to healthy mucosa. Another vaginal tablet is formulated from the combination of poly(acrylic acid) with hydroxypropyl methylcellulose and ethylcellulose (111). Other polymer combinations evaluated for potential bioadhesive vaginal delivery include poly(acrylic acid) and sodium carboxymethyl cellulose with Avicel PH102 (methylcellulose) as the diluent (112). Insulin has been formulated in a cross-linked poly(acrylic acid) gel and found to be adsorbed onto the vaginal surface of alloxan-induced diabetic rats and rabbits (113).

Emulsion-based formulations with bioadhesive properties also have been designed to deliver antifungal agents, although little has been reported in the literature (78). Bioadhesive microparticles used in nasal and oral delivery have the potential for further development of intravaginal delivery systems. The mucoadhesive benzyl ester of hyaluronic acid has been used in preparing microspheres for the intravaginal delivery of salmon calcitonin to rats (114). Replens[®], which has been marketed as a bioadhesive moisturizer and which remains in the vagina for 2–3 days, consists of a bioadhesive cross-linked polycarboxophil (115). Carbopol 934 polymer could be a good bioadhesive candidate for clinical application in the intravaginal delivery of spermicidal agents (44).

Liposomes, a novel drug delivery system, are widely applied in the topical treatment of diseases, including vaginal diseases. Their applications in contraceptive systems for the intravaginal administration of progesterone (116) and interferon- α (117) (or metronidazole) (118) for the genital papilloma virus infections were previously reported.

DRUG CANDIDATES FOR VAGINAL ADMINISTRATION

Antimicrobials

Antimicrobials, along with antifungals, have been important drug candidates for the treatment of vaginal diseases, such as bacterial vaginosis. Earlier researches on antimicrobials, such as penicillin and sulfanilamide, has been reviewed (22). Evaluations have been made on such drugs as metronidazole (119–121), clindamycin

(122, 123), feticonazole (124), and clotrimazole (124, 125). Metronidazole has been prescribed for the treatment of amoebiasis, trichomoniasis, lambliasis, and anaerobic infection (121). It is administered vaginally as a gel, normally twice a day every 12 h for 7 days for the treatment of bacterial vaginosis. The gel results in lower serum concentrations with negligible adverse systemic effect (119). Metronidazole's low lipid solubility probably contributes to its poor vaginal absorption (120). A comparison of vaginal and oral drug delivery of metronidazole from a film-coated tablet showed that the maximum serum concentrations attained by vaginal delivery are only sufficient to kill the most susceptible anaerobes (121). One recent study confirmed that liposomes could be used as a novel delivery system for metronidazole in the treatment of vaginal infections (118).

Clindamycin also is indicated for the treatment of bacterial vaginosis. Its efficacy as a 2% cream is similar to oral metronidazole treatment (122). Measurable amounts of clindamycin, corresponding to frequency of application, have been detected systemically at levels well below those of intravenous delivery (123). Gentamicin is an additional aminoglycoside that was evaluated for vaginal administration in ovariectomized rats (126). The results indicated the following order of absorption enhancers by their effectiveness: 1% palmitoylcarnitine > 0.5% lysophosphatidylcholine > 1% laureth-9 > 10% citric acid. Severity of desquamation of the vaginal epithelium were scored as lysophosphatidylcholine = laureth-9 > palmitoylcarnitine > citric acid.

The market for vaginal candidiasis treatments has been revamped in recent years due to the availability of OTC products. Recently, oral antifungal agents, i.e., ketoconazole, have been approved for treatment of vaginal candidiasis. Earlier research that compared vaginal feticonazole to oral clotrimazole (125) and vaginal clotrimazole to oral fluconazole (100) have found them equally effective and well tolerated as compared to the oral product used for comparison. An important consideration in the choice of oral vs. vaginal treatment is the contraindication of oral dosage forms during pregnancy. Vaginal treatment for recurrent vaginal conditions may be a good alternative in such a case (127).

Anticancer Agents

Intravaginal investigations into the local treatment of cervicovaginal cancers have made some progress over recent years. [³H]-Feticonazole has been evaluated in normal cervicovaginal mucosa, cervical carcinoma, and relapsing vulvovaginal candidiasis, and was found to be devoid of risk to patients (128). For patients with vaginal

rhabdomyosarcoma and residual vaginal disease following surgery and chemotherapy, the effects of high-dose irradiation from vaginal molds loaded with iridium¹⁹² were examined (129). Individualized molds were made with rapid setting silastic foam and loaded with iridium wires. The patients treated remained well and disease-free for 7 years. The pharmacokinetics properties of ciclopirox olamine have been evaluated after vaginal application to rabbits and patients. The intravaginal absorption was found to be low while the penetration of drug was found in deep tissue. These results led to good local and systemic tolerability (130). Cisplatin suppositories have been tested preoperatively via vaginal administration (131). The Cisplatin penetration of the tumor surface needs further improvement in order to achieve effective local chemotherapy.

Contrary to cancer treatment, cervicovaginal cancers are linked to vaginal pessary use. Review of cancer cases found that tumors occurred at sites of ring insertion. Although chemical carcinogenesis cannot be ruled out, chronic local infection may be the main etiologic factor. The severity of cancer cases has declined in recent years due to the availability of more advanced surgical and radiation treatments with minimal complications (132).

Prostaglandins

For many years, prostaglandins, primarily prostaglandin E₂ (PGE₂), have been studied for cervical ripening and induction of labor as well as an abortifacient. Most of the prostaglandin delivery systems have been in the form of suppositories or pessaries (133–143). More recent work with pessaries and gels has been done due to the use of prostaglandins as an alternative to surgical abortions.

Early work with PGE₂ formulated a sustained-release pessary that used a swelled, cross-linked polymer hydrogel (143). Further work was conducted using a semicrystalline poly(ethylene oxide) and poly(urethane) hydrogel swollen with PGE₂ solution (144). The controlled release of PGE₂ and the cervical score showed a linear release, suggesting the advantage of control over cervical ripening (145). Pessaries provided greater control in labor induction (146), (more favorable than intracervical gels (147)), had high efficacy and low incidence of side effects (148), and showed a reduction in cesarean rates associated with artificial rupture caused by oxytocin infusion (149). Although PGE₂ has been shown to initiate active labor and reduce the need for oxytocin, it has been shown to cause uterine hyperstimulation or fetal heart rate abnormalities, which are reversed with removal of the pessary (150). Tablet forms of PGE₂ are shown to be more chemically stable and cost effective (151, 152). Additionally, the case

of use may allow for shortening of postdate pregnancies in a safe and effective manner on an outpatient basis (153).

In addition, PGE₂ has been formulated as a gel. A comparison of tablets and a triacetin-base gel showed more favorable induction with the gel (154). The use of PGE₂ gel in women with prelabor spontaneous rupture of membranes, significantly improved the time of delivery without influencing the cesarean section rate or fetal-maternal infective morbidity (155). The intravaginally administered gel was more efficacious than that given intracervically (156). In regards to a regimen, either 12 h or 6-hourly, the majority of 12-hourly subjects achieved labor after a single dose, but the induction delivery interval was similar in both groups (157).

Due to its labor-inducing characteristics, prostaglandins also have been used as abortifacients. PGE₁, as a vaginal pessary, has been combined with the oral antiprogesterin, mifepristone (RU486), and has been found to be a safe, efficient nonsurgical outpatient method of termination (158). The PGE₂ product, originally intended for the treatment of GI ulcers caused by nonsteroidal antiinflammatories, was shown to be a safe and low-cost method. Misoprostol alone has been used for the induction of labor with females with late fetal death (159). Attention of the medical profession and the news media has resulted in the use of misoprostol and methotrexate for early abortion. In this application, methotrexate, originally used as a chemotherapeutic agent in cancer and arthritis, is given intramuscularly followed by intravaginal misoprostol 3 days later. This is an effective abortion method for a gestation period of 56 days or less (160).

Spermicides

Spermicidal activity in the vagina is intended for fertility control, by eliminating the motility of sperm and ultimately killing them. Spermicides have become more popular with the rise in social awareness and prevention of sexually transmitted diseases. Many compounds have been evaluated for spermicidal activity. As mentioned, nonoxynol-9 and octoxynol are predominantly available in the United States. A few products that have been evaluated include alkyloxynol-741, which was tested in stump-tailed macaques for spermicidal activity, and gramicidine, which is used as a spermicidal agent in Russia but not in the United States. Alkyloxynol-741 was compared with nonoxynol-9 and chlorhexidine, using a dissolvable polyvinyl alcohol film, and found to be an inexpensive alternative in countries where nonoxynol-9 may not be readily available (161). The combination of nonoxynol-9 and EDTA in a gel formulation, developed from carbopol 934 polymer showed a significant

enhancement of efficacy in fertility control (44). A tablet form drug delivery system fabricated by incorporating nonoxynol-9 into polyvinylpyrrolidone, was reported to provide a short- and long-term release of nonoxynol-9 and produce an immediate and extended enhancement of the contraceptive properties (162). Protectaid, a contraceptive sponge marketed in Canada, contains sodium cholate, nonoxynol-9, and benzalkonium chloride. Sodium cholate itself has been shown to exhibit strong spermicidal and antiviral activity, and offers a new and modern protective method (2828 163). A serine protease from sperm, 44-acetamidophenyl-4-guanidinobenzoate, inhibits acrosin activity and has been found to be more potent and less irritating than nonoxynol-9, as well as providing protection against HIV (164).

Various studies found that the absorption of nonoxynol-9 through the vaginal membrane was very slow and suggested a dependence of molecular weight of the oligomeric components that make up the spermicide (165, 166). Permeation studies have found the hydrophilic–lipophilic balance (HLB) of the oligomers to play a role as well (36). In delivery gel made of calcium chloride cross-linked alginate containing 3% of nonoxynol-9, it was found that pH of delivery gel had a significant effect on spermicidal efficacy of nonoxynol-9 (167). This behavior could be attributed to nonoxynol-9 micelle formation.

Steroids

The vaginal delivery of steroids for urogenital symptoms has been shown to be more appropriate than oral and parenteral administration. Hormone replacement therapy is indicated for peri- and postmenopausal women suffering from vasomotor symptoms, vaginal dryness, and discomfort due to urogenital atrophy and other related symptoms of hormone deficiency. Steroids, progesterone and estrogen, have been used for many years to treat a variety of physiologic conditions, including hormonal replacement and contraception. As an alternative to oral estrogen replacement, vaginal estrogen cream is an effective treatment for vaginal atrophy (168). Use of estradiol cream has been effective for atrophic vaginitis (53) and also for endometrial proliferation and hyperplasia if coadministered with progestins (169). Systemic absorption of progestins could have the risk of endometrial hyperplasia.

Like estrogen, progesterone has been delivered via the vagina as creams, pessaries, and vaginal rings. Vaginal absorption and local redistribution of progesterone was observed in a study using young female pigs (170). Vaginal delivery has shown enhanced progesterone delivery to the uterus when compared with a standard

intramuscular regimen (171). Micronized progesterone in a nonliquefying vaginal cream is promising (172, 173). For systemic delivery of progesterone to the genital organs, doctors have prescribed to their patients a suppository compound of progesterone and cocoa butter. A lactose-based progesterone tablet has been designed to deliver biologically effective amounts of progesterone for up to 48 h (77). These tablets form a milky suspension and stay resident in the vagina for a longer period of time, making them ideal for the treatment of menstrual irregularities, functional uterine bleeding, luteal phase defects, premenstrual tension, infertility, and osteoporosis. A recent study demonstrated that a “first uterine pass effect” occurred when progesterone was delivered intravaginally, thereby providing an explanation for the unexpectedly high uterine concentrations relative to the low serum concentration observed (174). Application of liposomes as the vaginal delivery system for progesterone to achieve contraceptive efficacy was successfully demonstrated (116). The combined use of progesterone delivered from an intravaginal-targeted drug delivery system and estradiol delivered from a transdermal therapeutic system were found to be very effective in producing artificial cycles (95).

Absorption and secretion characteristics of sodium prasterone sulfate have been evaluated in rats after vaginal administration. The absorption was significantly affected by the estrus cycle and the progression of the pregnancy (175).

Proteins and Peptides

Research on the intravaginal delivery of peptides and proteins has focused on insulin and gonadotropin-releasing hormones (GnRH) and their absorption into the systemic circulation. Insulin and thyroid-stimulating hormone have been shown to achieve some absorption from the vagina of rats and rabbits, but with a high dependency on the estrus cycle (113). Hydrophilic molecules, like insulin and GnRH, may be absorbed through intercellular channels, hence absorption would be greater when the epithelium is thinner (77, 176). As commonly observed with protein and peptide research, an enhancer is often needed to assist in absorption. The enhancers are limited in human testing; thus, most of the preliminary research must be done in animal models, such as the rat and rabbit (77). Vaginal administration of insulin was found to increase hypoglycemia in rats when using enhancers such as Na taurodihydrofusidate, polyoxyethylene-9-lauryl ether, lysophosphatidylglycerol, lysophosphatidyl choline, and palmitoylcarnitine chloride (177). Other therapeutic agents that have been investigated include leucine enkephalin (66), salmon calcitonin (115, 178), and

recombinant human relaxin (179, 180). Relaxin, structurally related to insulin, was formulated as a 3% methylcellulose gel for intravaginal delivery. In this form, it had limited permeability through nonpregnant rabbit and rhesus monkey vaginas.

Much work has been done using luteinizing hormone releasing hormones (LHRH) analogs, particularly leuprolide. Initial work with leuprolide found greater potency in rats via vaginal administration over rectal, nasal, and oral administration (181). Enhancement of absorption by organic acids (citric, succinic, tartaric, and glycocholic) increased bioavailability by 20%. The vaginal absorption from jellies was found to be a practical dosage form. Additional investigation of the organic acids used for enhancement was found to work by the acidifying and chelating ability (182). Citric acid also was shown to loosen the blood–vaginal epithelium barrier. The down regulation of the pituitary by chronic intravaginal treatment of leuprolide exhibited regression of hormone-dependent mammary tumors in rats (183–185). The vaginal route appears to be the preferred route according to a recent presystemic metabolism study of first-order LHRH degradation in rabbit homogenates (186). The degradation half-life of vaginal homogenates was 9–12 times longer than that of rectal homogenates and 3–4 times longer than that of nasal homogenates.

Vaccines, Antigens, and Gene Delivery

Factors that have a significant impact on immune responses are the route and method of vaccine or antibody delivery (187). Since the recognition of acquired immunodeficiency syndrome (AIDS) in the early 1980s, researchers have focused on the discovery of pharmacological agents for the treatment and ultimate cure of AIDS, as well as on preventing the spread of the virus. Mucosal infection via the vagina and rectum are reportedly two of the major pathways through which HIV and other sexually transmitting viruses are disseminated (188, 189). Mucosal immunity has been considered as the first line of immunological defense against these pathogens to prevent the systemic infection. The important factors to be considered in the development of vaccines are protection with a minimum number of administrations and a practicability of the approaches in inducing immunity at the mucosal surface (81, 190). Consequently, studies were conducted to elucidate the effects of variations in the routes of immunizations on the type and extent of mucosal response (191). Mucosal immunity in the female reproductive tract was reportedly influenced by immunoglobulins (Igs), cytokines, and reproductive hormones. The types of responses elicited following a DNA

immunization were found to depend on both the identity of the antigen and the route of DNA administration. The epidermal delivery route, including vaginal mucosa, was found to be more efficient in terms of dosage requirements (192, 193). When the effects of exogenous hormones on reproductive tract immunity were evaluated in women on oral contraceptive pills (OCPs), the mean values of IgA in the cervical mucus of women on OCPs were much greater than those in the naturally cycling women (194). The increased levels of IgA in the cervical mucus of women on OCPs may contribute to a lower incidence of sexually transmitted diseases. Using animal models, the transfection of mucosal tissues by gene–gun administered plasmids was demonstrated *in vivo*, and vaginal immunization of human growth hormone was noted to yield a higher titer of cervicovaginal antibodies than other routes of immunization (88).

DNA-based vaccines have been recently developed for immunization to overcome the deficiencies of antigen-based vaccines. The major sites of delivery for DNA-based immunization include the oral, nasal, rectal, and vaginal mucosae (195, 196). The ability of a hepatitis B surface antigen-encoding plasmid to induce responses in mice through the various routes of delivery was compared (197). It was reported that delivery through the vaginal route still produced a cytotoxic T lymphocyte activity, even though it failed to induce antibodies. A human simian virus 1 (HSV) vaccine was tested as an aqueous solution or gel intranasally, vaginally, and subcutaneously in guinea pigs (198). The gel system used was a controlled release carbopol gel. The animals were challenged 3–5 weeks later with only the subcutaneous response producing IgG and IgA. The nasal and vaginal routes showed that the vaccine could take up and elicit antibodies, thereby slightly reducing the severity of the disease, but showed no superiority to the subcutaneous route. In another study, rats were immunized with a synthetic peptide from a HIV envelope glycoprotein and shown to have greater IgG and IgA response with an enhancer, lysophosphatidyl glycerol (199, 200). The serum antibodies from subcutaneous and intravaginal delivery were able to recognize the glycoprotein (HIV 1 gp120), but no neutralizing activity against the virus was seen. An antigen delivery system of lysophosphatidylcholine and degradable starch microspheres demonstrated potential intravaginal delivery to sheep (199, 200). If the vagina is capable of mounting an immune response, antibodies in genital secretions may be able to reduce the transmission of HIV. Intravaginally administered tracers using (fluorescein isothiocyanate) (FITC) bovine albumin, FITC-horseradish peroxidase, and FITC-horse ferritin have shown the vagina and cervix to be major sites of protein uptake (201).

Lactobacilli from the female genital tract have been developed as a vehicle to deliver continued doses of foreign antigen to the vaginal mucosa surface with the aim of stimulating a local immune response (202). The lactobacillus fermentum was chosen for genetic manipulation and delivered intravaginally in guinea pigs and was maintained for 5 days. Despite the short period, the novel vaccination approach shows potential for stimulating mucosa immunization. Horse ferritin was combined with aluminum hydroxide, muramyl dipeptide, monophosphoryl lipid A, dimethyl dioctadecyl ammonium, and cholera toxin (203). The aluminum hydroxide combination was found to be the most effective. However, the doses of antigen used were larger than normal, and consequently the drug combination may be inefficient at more realistic dosages. Additional work with mouse ferritin has shown pelvic immunization at nonmucosal sites to be very effective in stimulating an IgA response in the female reproductive tract, more so than intravaginal delivery because of possible involvement of iliac lymph nodes not associated with the vagina (204).

As a potential means of treatment of gynecological conditions, *Candida albicans* vaccine was developed and an antibody response after intravaginal application of vaccine and effects on recurrent urinary tract infections were evaluated (205, 206). Serum antibody to some of non-*E. coli*, but no antibody to *E. coli* were expressed (207). The vaccine was well tolerated and invites further development. Another evaluated vaccines contained inactivated polio vaccine delivered by intravaginal, intrauterine, mesopharyngeal, and intramuscular routes. The predominant secretory antibodies to polio virus in the vagina were found to be IgA and IgG in the uterus. The genital tract is immunologically reactive and may play a role in protection against other infections such as gonococcus and genital herpes (208). For veterinary use, dairy cattle research has directed attention to bovine herpes virus type 2, which causes ulcerative lesions in teats and udders. Vaccinations subcutaneously and intravaginally have been shown to be beneficial in reducing the severity of the infection and show potential for a vaccine for dairy cattle (209).

Anti-inflammatory Agents and Others

Bromocriptine has been used in the treatment of hyperprolactinaemic women (210). Drug in tablet form was administered intravaginally and found well absorbed from the vagina, with avoidance of side effects. For Benzydamine, a nonsteroidal anti-inflammatory with local anesthetic and analgesic properties, mouthwash, dermal cream, and vaginal douche have been formulated and evaluated for local therapy (211). Another chemical entity

that has been researched for intravaginal delivery is tranexamic acid, an antifibrinolytic drug usually given by mouth for the treatment of menorrhagia associated with intrauterine devices (IUD). The intravaginal delivery of tranexamic acid was found well tolerated with avoidance of GI side effects (212).

DRUG DELIVERY—TOPICAL AND TRANSDERMAL ROUTES

Kenneth A. Walters

An-eX Analytical Services Ltd, Cardiff, United Kingdom

INTRODUCTION

Over the past 3 decades there have been significant advances in the science of dermal and transdermal drug delivery. Much of this research has been reviewed and published elsewhere (1–9). This chapter, therefore, will concentrate on more recent innovations and research directions. The author recognizes that the review will not be exhaustive and apologizes unreservedly for any omissions, either deliberate or accidental. Thus, the reader interested in the recent developments in physical methods of skin permeation enhancement, such as iontophoresis, electroporation, and sonophoresis, is directed to the excellent reviews of Banga (5), Lai and Roberts (10), and Kost et al. (11), and the research papers of Guy et al. (12), Ilic et al. (13), and Lombry et al. (14). Likewise, detailed descriptions of the formulations used in dermal and transdermal drug delivery will be omitted because they are fully discussed elsewhere (4). Mathematical aspects of percutaneous absorption and its prediction will be briefly mentioned but readers wishing to delve into the complexities of this subject should consult the detailed analyses of Pugh et al. (15) and Roberts et al. (16). This chapter will concentrate on recent developments in our understanding of the skin barrier and the novel chemical methodologies used to reduce barrier function. Technologies that may be useful in reducing adverse local reactions, often associated with dermal and transdermal drug delivery, will be discussed. There will be a brief review on innovative drug delivery systems. Finally, the recent regulatory initiatives in dermatological therapy will be described.

STRATUM CORNEUM DEVELOPMENT, MICROSTRUCTURE, AND BARRIER FUNCTION

Stratum Corneum Development

The development of the stratum corneum involves several steps of cell differentiation, which has resulted in a structure-based classification of the layers above the basal layer (the stratum basale). Thus, the cells progress from the stratum basale through the stratum spinosum, the

stratum granulosum, and the stratum lucidum to the stratum corneum (17). Cell turnover from stratum basale to stratum corneum is estimated to be on the order of 21 days. The exact mechanism underlying the initiation of keratinocyte differentiation is not fully understood. It is known that protein kinase C and several keratinocyte-derived cytokines may play a regulatory role in the differentiation process (18, 19).

In the outer cell layers of the stratum spinosum, intracellular membrane-coating granules (100–300 nm in diameter) appear within the cells. Within these granules lamellar subunits arranged in parallel stacks are observed. These are believed to be the precursors of the intercellular lipid lamellae of the stratum corneum (20, 21). In the outermost layers of the stratum granulosum the lamellar granules migrate to the apical plasma membrane where they fuse and eventually extrude their contents into the intercellular space (20). The extrusion of the contents of lamellar granules is a fundamental requirement for the formation of the epidermal permeability barrier (22, 23). Thus, the entire process of epidermal terminal differentiation is geared toward the generation of the specific chemical morphology of the stratum corneum. As a result, the end products of this process are the intracellular protein matrix and the intercellular lipid lamellae.

The cornified cell envelope is the outermost layer of a corneocyte, and mainly consists of tightly bundled keratin filaments aligned parallel to the main face of the corneocyte. The envelope consists of both protein and lipid components in that the lipid is attached covalently to the protein envelope. The envelope lies adjacent to the interior surface of the plasma membrane (24). The corneocyte protein envelope appears to play an important role in the structural assembly of the intercellular lipid lamellae of the stratum corneum. The corneocyte possesses a chemically bound lipid envelope comprised of *N*- ω -hydroxyceramides, which are ester linked to the numerous glutamate side chains provided possibly by both the α -helical conformation and β -sheet conformation of involucrin in the envelope protein matrix (25, 26). In the absence of *N*- ω -hydroxyceramides, the stratum corneum intercellular lipid lamellae were abnormal and permeability barrier function was disrupted (27).

The Intercellular Lipids

The stratum corneum intercellular lipids exist as a continuous lipid phase occupying about 20% of the stratum corneum volume and arranged in multiple lamellar structures. They are composed of cholesterol (27%) and ceramides (41%), together with free fatty acids (9%), cholesteryl esters (10%) and cholesteryl sulfate (2%) (28) (Table 1). Phospholipids, which dominate in the basal layer, are converted to glucosylceramides and subsequently to ceramides and free fatty acids, and are virtually absent in the outer layers of the stratum corneum. Eight classes of ceramides have been isolated and identified in human stratum corneum (29, 30) but the functions of the individual ceramide types are not fully understood. Similarly, the exact function of cholesterol esters within the stratum corneum lamellae is also elusive but it is theoretically possible that cholesterol esters may span adjacent bilayers and serve as additional stabilizing moieties.

Overall, the intercellular lipid lamellae are highly structured, very stable, and constitute a highly effective barrier to chemical penetration and permeation. Considerable information on lipid structure within the stratum corneum has been generated by Bouwstra, Poncet, and colleagues using small angle X-ray diffraction and transmission electron microscopic techniques. These and earlier studies have shown that the lipid lamellae of the stratum corneum are orientated parallel to the corneocyte surface and have repeat distances of approximately 6.0–6.4 nm and 13.2–13.4 nm. In more recent studies on lipid packing (31), the Leiden group evaluated lipid

organization of the stratum corneum using electron diffraction and found that although the majority of lipids in the intercellular space were present in the crystalline state, there were some lipids existing in the gel state that had a slightly looser hexagonal packing arrangement in the outer layers of the stratum corneum.

Stratum Corneum Barrier Properties

Systematic evaluation of the skin permeability of many compounds has demonstrated that the intercellular lipids of the stratum corneum are essential for normal skin barrier function. It is clear that the major route of permeation across the stratum corneum is through the continuous intercellular lipid lamellae. Thus, the rate at which permeation occurs is largely dependent on the physicochemical characteristics of the penetrant, the most important being the relative ability to partition into the intercellular lipid lamellae and molecular size. Three major variables account for differences in the rate at which different compounds permeate the skin: the concentration of permeant applied, the partition coefficient of the permeant between the applied vehicle and the stratum corneum, and the diffusivity of the compound within the stratum corneum. A plot of the log of the skin permeability rate versus permeant lipophilicity is usually sigmoidal, and reflects the existence of both lipophilic and hydrophilic barriers. This suggests that compounds with partition coefficients indicating an ability to dissolve in both oil and water (i.e., log P of 1–3) would permeate the skin relatively rapidly. This has been confirmed for a variety of compounds. Data illustrating the skin permeability of various nonsteroidal anti-inflammatory agents are shown in Fig. 1 (32).

Table 1 Lipids of the stratum corneum intercellular space

Lipid	wt%	mol%
Cholesterol esters	10.0	7.5 ^a
Cholesterol	26.9	33.4
Cholesterol sulphate	1.9	2.0
Total cholesterol derivatives	38.8	42.9
Ceramide 1	3.2	1.6
Ceramide 2	8.9	6.6
Ceramide 3	4.9	3.5
Ceramide 4	6.1	4.2
Ceramide 5	5.7	5.0
Ceramide 6	12.3	8.6
Total ceramides	41.1	29.5
Fatty acids	9.1	17.0 ^a
Others	11.1	10.6 ^b

^aBased on C16 alkyl chain.

^bBased on MW of 500.

Mathematical Prediction of Permeation (Limitations)

Mathematical models relate skin permeability of exogenous molecules to physicochemical parameters of the permeant (octanol/water partition coefficients and molecular weight [a surrogate marker of molecular size]). Similar models for animal and human skin relate normalized equations of best-fit regressions based on:

$$\log P_{\text{calc}} = A + B \log K_{o/w} + C \cdot \text{MWt}$$

where P is the permeability coefficient, $K_{o/w}$ is the o/w partition coefficient, and MWt is the molecular weight.

Different values of A , B , and C have been derived depending on species (33) and dataset used (15). The models are significantly limited by the range of partition coefficients (log $K_{o/w}$ range -3 to ~ 6) and molecular weights (MWt range 18–765) of the datasets used, and

Fig. 1 Relationship between amount of drug absorbed through skin and compound octanol–water partition coefficient (increasing lipophilicity). Open circles: salicylates; closed circles: other nonsteroidal anti-inflammatory agents. (Redrawn from Ref. 32.)

anomalous values can be generated. As the boundaries of the dataset used are approached, the predictions become increasingly unrealistic. For example, the Vecchia equation (33) for human skin predicts that a permeant with molecular weight of 500 and $\log K_{o/w}$ of 6 (not unusual for new drugs and cosmetic ingredients) will permeate skin at a rate of 1.3×10^{-2} cm/h, an order of magnitude faster than water or methanol. In addition, as these models are based on experiments in which permeants were applied in aqueous solution, their value in prediction of permeation from actual formulations applied under in-use conditions is further compromised. For example, while the predicted permeability coefficient for *N*-nitroso-diethanolamine is 1.5×10^{-4} cm/h, the experimentally determined value from isopropylmyristate was 3.5×10^{-3} cm/h (34). The predicted value for octyl salicylate is 1.35×10^{-7} cm/h, while the experimental values from a hydroalcoholic lotion were 4.7×10^{-6} cm/h (infinite dose) and 6.6×10^{-7} cm/h (finite dose), and from an oil-in-water emulsion 1.7×10^{-5} cm/h (infinite dose) and 6.6×10^{-7} cm/h (finite dose) (35).

Datasets continue to be accumulated and predictive methods continue to be refined. However, while mathematical predictions may be useful in the comparison of the behavior of closely related compounds, it is inappropriate to use them for risk assessment or formulation optimization purposes without relevant experimental verification.

CHEMICAL SKIN PERMEATION ENHANCEMENT

The success of dermatological or transdermal drug delivery systems depends on the ability of the drug to penetrate into and/or permeate through skin in sufficient quantities to achieve therapeutic levels. Over the past 2 decades, several chemical skin permeation enhancers have been designed, synthesized, and evaluated (1,2). Many of these enhancers including Azone[®] (1-dodecylazacycloheptan-2-one) and SEPA[®] (2-*n*-nonyl-1,3-dioxolane) have been discussed in full elsewhere (36). Newer enhancers include 1-[2-(decylthio)ethyl]azacyclopentan-2-one (HPE-101), 4-decyloxazolid-2-one (Dermac[™] SR-38), and dodecyl-*N,N*-dimethylamino isopropionate (DDAIP, NexACT 88) (Fig. 2).

HPE-101 is believed to have a similar mechanism of action to Azone and is very sensitive to the vehicle of application (37). Thus, although the enhancer significantly increased the urinary excretion of indomethacin following topical application to hairless mice, it was dependent on the application vehicle (37). When the enhancer was applied in solution in polar solvents, such as dipropylene glycol, triethylene glycol, diethylene glycol, glycerin, water, and triethanolamine, enhancement ratios varied between 1.5 and approximately 67-fold. However, when applied in solution in more lipophilic solvents, such as ethanol, isopropanol, oleyl alcohol, isopropyl myristate, or hexylene glycol, no enhancement was observed. These findings stress the importance of optimization of the delivery vehicle not only for the drug but also for the enhancer. Combinations of HPE-101 with cyclodextrins appear to be useful means to improve drug permeation across the skin (38). All of the available data, however, have been obtained

Fig. 2 Structures of the skin permeation enhancers HPE-101 (1-[2-(decylthio)ethyl]aza-cyclopentan-2-one), Dermac SR-38 (4-decyloxazolid-2-one), and NexACT 88 (dodecyl-*N,N*-dimethylamino isopropionate).

using hairless mice or other small laboratory animal skin. Small laboratory animals, especially the hairless mouse, can be uniquely sensitive to skin penetration enhancement and, as yet, the effectiveness of HPE-101 on human skin has not been reported.

Dermac SR-38 is one of a series of oxazolidinones, cyclic urethane compounds, evaluated as transdermal enhancers (39). The compound was designed to mimic natural skin lipids (such as ceramides), to be nonirritating, and to be rapidly cleared from the systemic circulation following absorption (40). In animal and human safety studies, Dermac SR-38 demonstrated a good skin tolerance (no observed irritancy or sensitization at levels of 1–10 wt%; moderate to severe irritation in rabbit at 100%), and a low degree of acute toxicity ($LD_{50}(\text{rat oral}) > 5.0 \text{ g/kg}$). The compound was evaluated for its ability to enhance the human skin permeation of diverse drugs from dermal and transdermal delivery systems. Data for minoxidil indicated an enhancer concentration-dependent effect for permeation enhancement. Dermac SR-38 was also found to enhance the skin retention of both retinoic acid when applied in Retin A cream, and dihydroxyacetone when applied in a hydrophilic cream (41).

NexACT 88 (dodecyl-*N,N*-dimethylamino isopropionate, DDAIP) is one of a series of dimethylamino alkanoates, reported to be biodegradable, which were developed as potential nontoxic skin permeation enhancers (42). Much of the early work was carried out using shed snake skin and it was found, using this model, that most of these compounds were equal to or more active

than Azone. Studies using human skin indicated that dodecyl-*N,N*-dimethylamino acetate (DDAA) was a more effective enhancer of absorption of propranolol hydrochloride and sotalol than was Azone (43). Structural optimization of the compounds led to the identification of the lead candidate DDAIP (44), which appeared to be more effective than DDAA. Mechanism of action studies indicated that the distribution of DDAIP in stratum corneum lipids was somewhat different to that of DDAA, suggesting that other interactions were contributing to the penetration enhancement effect. It is possible that in addition to its effect on stratum corneum lipids, DDAIP may interact with keratin and potentially increase stratum corneum hydration.

Other compounds have been identified and have undergone preliminary evaluation as potential skin penetration enhancers. The data are, however, very limited and these candidate enhancers are mentioned here solely for completeness. The biodegradable fatty acid esters of *N*-(2-hydroxyethyl)-2-pyrrolidone (decyl and oleyl) were synthesized and evaluated for enhancer activity using hairless mouse skin (45). Permeation of hydrocortisone was enhanced two-fold. The activity of *n*-pentyl-*N*-acetylprolinate as a skin permeation enhancer has been determined using human skin (46). The enhancement potential of several sunscreen agents, including padimate O, octyl salicylate, and octyl methoxycinnamate, has been evaluated with some success (47). Table 2 lists some of the more recent patent disclosures concerning skin permeation enhancement.

Table 2 Recent patents containing references to skin permeation enhancers

Patent no.	Enhancer	Assignee

ADVERSE LOCAL REACTIONS AND STRATEGIES FOR REDUCTION

Human skin is exposed to an environment that contains a variety of natural and synthetic compounds. Inevitably, dermal contact, either accidental or deliberate, will be made with a wide number of these compounds, many of which have the potential for inducing adverse cutaneous reactions, such as irritation and sensitization.

Adverse skin responses to chemical exposure are variable, may be immediate or delayed, and be of long or short duration. They may also be classified as irritant or allergic. Dermatological and transdermal formulations contain a complex mixture of active and inactive ingredients and it is important to appreciate that the cause of any adverse reactions may be a formulation additive (excipient) and not necessarily an active compound. Thus, for example, it is well known to those developing transdermal delivery systems that the pressure sensitive adhesive used to produce intimate contact with the skin is more likely to be the source of any cutaneous reactivity than is the drug. A further complication is that many of the inactive ingredients used in topical pharmaceutical dosage forms may have the ability to alter the barrier function of the skin, which in turn may enhance the percutaneous penetration not only of other formulation ingredients but also of subsequent exposure, either accidentally or deliberately, to chemicals.

Acute toxic contact dermatitis may be induced by a single application of a toxic material. One local inflammatory skin reaction is characterized by erythema and oedema. This type of reaction occurs following contact with materials such as acids, alkalis, solvents, and cleansers and is rarely associated with topical application of medicinal or cosmetic products. In contrast, irritant contact dermatitis (a superficial nonimmunologically based reaction) may occur after repeated exposure to many substances, including topical pharmaceutical agents. The reaction is usually localized to the site of exposure and usually diminishes after the stimulus has been removed. Some materials can stimulate an immune response following an initial topical application. Any future exposure may result in an inflammatory immune reaction, an allergic contact dermatitis, or sensitization.

There are two main sensitization reactions—immediate and delayed hypersensitivity. Immediate type hypersensitivity is the result of antibody–allergen interaction occurring in the skin; the reaction that develops is known as allergic contact urticaria. Delayed type hypersensitivity is the result of cell-mediated immunity and is the most frequently reported side effect of topical

drugs. Both epidermal and dermal cells play pivotal roles in irritation and sensitization. Keratinocytes in the viable epidermis synthesize and secrete proinflammatory mediators and cytokines that activate the biochemical cascade leading to inflammation. Angiogenesis may also play a role in the inflammatory response but although it is possible that inhibitors of neovascularization may modulate the response to irritants, this hypothesis has yet to be fully investigated and is far from commercialization.

Before a compound can induce an adverse skin reaction upon dermal exposure, it has to penetrate into and permeate across the stratum corneum. Many of the strategies for the reduction of adverse reactions are based on reducing or modulating this process.

Retention of Compounds on the Skin (Reducing Penetration)

It is well established that a principle driving force for diffusion across the skin is the concentration, or more accurately the thermodynamic activity, of the permeant in the donor vehicle. Thermodynamic activity is reflected by the concentration of the permeant in the donor vehicle as a function of its saturation solubility within that medium. The closer to saturation concentration, the higher the thermodynamic activity and the greater the escaping tendency of the permeant from the vehicle. This principle has been extensively utilized in pharmaceutical formulation development in attempts to enhance percutaneous absorption of drugs but it is seldom used to reduce absorption. This is not surprising because for the most part, efficacy is improved by greater drug delivery to the therapeutic target. However, in some instances it is preferable to retain the active compound on the skin surface or within the outer layers of the stratum corneum (e.g., insect repellants and sunscreens) and this may be feasible using the vehicle thermodynamic activity approach.

Retardation of penetration can also be facilitated by the use of physical barriers such as protective creams and polymeric materials. There is evidence that emollient creams may be useful as skin barriers, although the results reported to date are somewhat variable and contradictory (48). More recently, however, convincing data have been presented that demonstrated that a barrier lotion containing the organoclay quaternium-18 bentonite (5%) was extremely effective in reducing the occurrence of allergic contact dermatitis to poison ivy and poison oak (49). Other polymeric materials are designed as skin compatible barrier materials. The latter materials include polyolprepolymer [Penederm Inc. (Bertek Pharmaceuticals)] and MacroDermTM (MacroChem Corp.). Both types of polymeric

material have been shown to reduce the skin penetration and permeation of potentially irritating compounds.

The polyolprepolymer products are presently used in several cosmetics, over-the-counter, and prescription topical pharmaceutical products. An extensive toxicology package that illustrates that the polymers are safe in use is available. The polyolprepolymers are polyalkylene glycol-based polyurethanes and are available as three types (PP-2, PP-14, and PP-15) with varying solubility properties and associated formulation characteristics. They are, therefore, amenable to incorporation into a variety of formulation types, including gels, lotions, and creams. Convincing evidence indicates that the polyolprepolymers are capable of reducing the irritant response to retinoids in both laboratory animal and human models. In addition evidence has shown that these polymers are capable of modifying the skin distribution of applied materials, such as alcohols, hydroxy acids and salicylates.

The MacroDerm is low to moderate (2000–25,000 Daltons) in molecular weight, symmetrical polymers that consist mainly of polyoxyethylene and polyoxypropylene linked by alkylene chains and end-capped by long alkyl groups (Fig. 3). The proportionality of the polymer chain mix renders hydrophobicity or hydrophilicity to the resultant block polymer. MacroDerm L, a lipophilic polymer consisting of two units each of 15 polyoxypropylene molecules linked by an alkylene group and end-capped by stearyl chains, has been shown to reduce the skin permeation of various sunscreen agents and pharmaceutically active compounds. A more hydrophilic MacroDerm, in which the polyoxypropylene chains of MacroDerm L

Fig. 3 Structure of MacroDerm SA20C (Courtesy of Dr. S. Krauser, MacroChem Corporation).

Fig. 4 Structures of Azone and the analogues N0807 and N0915.

have been replaced with polyoxyethylene chains, has been shown to increase the efficiency of a moisturizing formulation. The flexibility in the selection of moieties on the MacroDerm compounds suggests that they may be compatible with and easy to incorporate into a variety of topical formulation types. Given the structure of the MacroDerm and the nature of the constituent moieties (together with their similarities to existing compounds such as poloxamers and other nonionic surfactants), it is unlikely that there will be any safety issues associated with their use.

Reduction of Skin Diffusivity (Reducing Permeation)

The finding that an analogue (N0915) of the skin permeation enhancer Azone (Fig. 4) retarded the penetration of metronidazole through excised human skin, presumably by increasing the order (decreasing fluidity) of the intercellular stratum corneum lipids (50), led to a rationalization of the mechanism of enhancement at the molecular level (51). The structured nature of the stratum corneum intercellular lipid lamellae relies heavily upon lateral cooperative interactions between adjacent ceramide head groups. Enhancers such as Azone intercalate the matrix, but only provide a matching cooperative site on one side of the head group. On the other hand, the Azone analogue N0915, which has cooperative sites on both sides of the head group and retards permeation, while analogue N0807, which has electronegative sites on both sides of the head group, is a more effective enhancer than Azone. In addition, both Azone and N0807 have a preferred bent head group conformation which will disrupt packing of alkyl chains and increase the possibility of permeable defects. This basic concept was refined in the logical design of a series of molecules that were specifically targeted at retardation of skin permeation.

Experiments have been conducted on two of these compounds to determine their penetration retardation effect on two compounds, hydrocortisone and diethyl toluamide (DEET) (52). Fig. 5 shows that the retarders could reduce the permeation of hydrocortisone, while

Fig. 5 Effects of Azone and the developmental retarding compounds 4-F2 and 2-F2 on permeation of hydrocortisone across human skin.

Azone, as expected, slightly increased permeation. Similarly, while Azone enhanced permeation of DEET, both retarder compounds reduced permeation. Although these data provide initial validation of the basic hypothesis for the mechanism of skin modulation, much remains to be accomplished before these compounds can be considered as viable strategies for irritation or sensitization reduction.

Miscellaneous Strategies for Modulating Skin Irritation

Many naturally occurring plant extracts are reputed to possess anti-irritant properties and have been recommended for use in cosmetic formulations. These include such diverse mixtures as tea tree oil, borage seed oil, Paraguay tea extract, Kola nut extract, oil of rosemary, and lavender oil. It is, however, difficult to standardize plant extracts and there may be a great deal of lot-to-lot variability in constituents. Understandably, this makes identification and isolation of any specific active constituent complex and laborious. The extracts may be oily or hydrophilic and contain compounds such as α -bisabolol, xanthines, polyphenols, and phytosterols. There is great potential in the use of plant extracts for irritation and sensitization reduction. This has been established within the cosmetic industry, and interest here has stimulated activity into reducing variability by more consistent cultivation techniques and more standardized extraction methods.

Strontium nitrate (Cosmederm-7™) has been shown to dramatically reduce the sensory irritation and erythema produced following application of a 70% free glycolic acid peel. It also has been shown to be effective in suppressing histamine-induced itch. Although the mode of action is unclear, the active principle appears to be elemental strontium in its free ionic form. It is postulated that the mode of action involves the potential ability of strontium to block neurogenic inflammation at type C neurons or nociceptors (53). It is interesting to note that the potential mechanism of action of strontium, involving nociceptor blockade, is also the mechanism by which capsaicin (the compound which renders chilli peppers “hot”) is believed to provide relief in several painful conditions, such as pruritis, postherpetic neuralgia, and diabetic neuropathy. Various analogues of capsaicin have been synthesized and evaluated for anti-inflammatory activity with varying degrees of success (54). However, it is important to appreciate that although the strategy of blocking sensory neurones will inhibit the sensation of pain, it will not inhibit the inflammation associated with an irritation reaction.

A combination of compounds, including oleic acid, a short chain length alcohol, and a glycol, all gelled with a carbomer, has been found to reduce inflammation associated with the topical application of several chemical species (CELLEDIRM, Cellegy Pharmaceuticals, Inc.) (55). This formulation has been patented with the major claim that the use of a combination of oleic acid and glycerol provides skin penetration enhancement while reducing irritation potential (when compared with, for example, oleyl alcohol). CELLEDIRM has been shown to reduce inflammation by up to 40% in animal models challenged with potent irritants or allergens. All the excipient ingredients within CELLEDIRM are either generally accepted as safe (GRAS) status or have been used in various pharmaceutical or cosmetic products. Cellegy Pharmaceuticals plans to utilize CELLEDIRM in the development of several pharmaceutical, dermatological, and transdermal formulations.

NOVEL DELIVERY SYSTEMS IN DERMATOLOGICAL AND TRANSDERMAL THERAPY

In addition to traditional dermal and transdermal delivery formulations, such as creams, ointments, gels, and patches, several other systems have been evaluated. In the pharmaceutical semisolid and liquid formulation area, these include sprays, foams, multiple emulsions, microemulsions, liposomal formulations, transfersomes,

niosomes, ethosomes, cyclodextrins, glycospheres, dermal membrane structures, and microsponges (56–58). Many of these novel systems use vesicles to modulate drug delivery. Novel transdermal formulations include soft patches, microneedles, and powder delivery systems.

Semisolid Vesicular Systems

Mezei first suggested that liposomes may be useful drug carrier systems for the local treatment of skin diseases (59). The suggestion was based on drug disposition data obtained following topical application of the steroid triamcinolone acetonide incorporated in phospholipid liposomes formulated as lotions or gels. Encapsulation of triamcinolone acetonide into liposomes resulted in a vehicle-dependent 4.5- to 4.9-fold increase in the amount of drug recovered from the epidermis. The work of Mezei suggested that application of the dermatological drugs in liposomal form compared to conventional formulations led to increased drug concentration in the skin and subcutaneous tissues and decreased biodisposition in plasma and remote sites. These encouraging early observations were followed by several confirmatory research and clinical investigations, most notably those of Weiner's group at the University of Michigan (60) and Korting's group at Ludwig-Maximilians University in Munich (61). Many other studies have indicated the potential of phospholipid liposomes to increase the skin content of topically applied drugs. Liposomes also have been prepared from lipid mixtures similar in composition to the stratum corneum intercellular lipid (62).

Another vesicle system that has been investigated for potential modification of skin permeation are niosomes (63). Niosomes are composed of nonionic surfactants, such as polyoxyethylene alkyl ethers, and may be prepared as single or multilamellar vesicles. Surfactants of this type are known to enhance skin permeation and this is likely to play a role in any modification of permeation using these vehicles. The effect of nonionic surfactant vesicles on the skin permeation of estradiol was shown to be dependent on the physical state of the niosome. On the other hands niosomes prepared from polyoxyethylene(3)stearyl ether and existing in the gel state did not increase estradiol permeation, and those prepared from polyoxyethylene(3)-lauryl ether and polyoxyethylene(10)oleyl ether, both existing as liquid crystalline vesicles, significantly enhanced transport. Further experiments in which the skin was pretreated with unloaded niosomes indicated that the enhanced transport of estradiol from drug-loaded vesicles was not wholly a result of surfactant-induced

penetration enhancement. The authors postulated that niosomes fused at the surface of the stratum corneum and generated high local concentrations of estradiol which resulted in increased thermodynamic activity of the permeant in the upper layers of the stratum corneum.

Vesicle systems, described as ethosomes composed of phospholipid, ethanol, and water, have been shown to enhance the transdermal delivery of minoxidil and testosterone when compared to more traditional formulations (Fig. 6) (57). The quantities of drug penetrating into and permeating through nude mouse skin *in vitro* were significantly greater from the ethosome systems than from appropriate control vehicles. Furthermore, when evaluated in rabbits *in vivo*, ethosomal transdermal patch systems produced higher testosterone plasma levels than a commercial patch. A tentative synergistic mode of action was proposed in which the ethanol disrupted the stratum corneum intercellular lipid, allowing the flexible ethosome to penetrate and possibly permeate the stratum corneum. The ethosome may subsequently fuse with skin lipids and release its drug content. The authors also point out that there may be a follicular contribution to the enhancement effect. It is interesting and important to note that there was no observed acute or cumulative irritancy (in rabbits) associated with the use of the ethosomal system.

Fig. 6 Minoxidil permeation from ethosome systems and appropriate control vehicles. Data are expressed as the cumulative permeation across male nude mouse skin *in vitro* over 24 h. (Figure plotted from data given in Ref. 57.)

The precise mode of interaction between lipid vesicles and skin remains unclear. There is considerable doubt about the ability of whole vesicles to permeate intact stratum corneum. The majority of evidence suggests that vesicles can penetrate the outer cell layers of the stratum corneum where desmosomal linkages have become disrupted and presumably, the keratinocytes are less tightly bound and surrounded by a mixture of intercellular lipid and sebum. However, continuing diffusion of vesicles through the approximately 60 nm intercellular space of the deeper layers of the stratum corneum seems unlikely. Current thinking suggests that lipid vesicles fuse with endogenous lipid either on the surface or in the outermost layers of the stratum corneum. The fusion is followed by structural changes in the deeper layers of the stratum corneum, as evidenced by freeze-fracture electron microscopy and small angle x-ray scattering techniques. These structural changes are presumed to be the result of intercellular diffusion of vesicle lipid components (not intact vesicles) to the deeper layers, as well as interaction with and disruption of endogenous lipid lamellae. It is simple to postulate that this interaction/disruption of lipid lamellae will lead to an increase in skin permeation rates but this does not explain the observed increase in skin retention of permeants. Apparent increased skin retention may be an artefact from exogenous lipid depot formation on the skin surface. On the other hand, formations of lipid aggregates, possibly comprised of mixtures of endogenous and exogenous lipid, observed in deeper layers of the stratum corneum may provide a reservoir for topically applied drugs.

Cevc and Blume (64), however, suggested that it was possible for whole vesicles to cross intact stratum corneum. The basic premise for this hypothesis was the driving force provided by the osmotic gradient between the outer and inner layers of the stratum corneum and the development of specific mixes of lipids to form modified liposomes termed transfersomes. The requirement for the osmotic gradient to be maintained suggests that transfersomes will not function in occlusive conditions and careful formulation is necessary. Due to their unique structure (a mix of phosphatidyl choline, sodium cholate, and ethanol), transfersomes are reputed to be very flexible vesicles and capable of transporting their contents through the tortuous intercellular route of the stratum corneum. The application of the corticosteroids triamcinolone acetonide, dexamethasone, and hydrocortisone encapsulated in transfersomes resulted in more reliable site specificity for the drug and, therefore, less potential for adverse side effects (65).

Novel Transdermal Systems

In terms of overall composition, traditional transdermal patch systems have changed little in the past few years. The modifications that have been made are, for the most part, refinements of the materials used in their construction (Table 3). This is the case for the “soft” patches that consist of thin flexible films containing a known amount of drug (66). The soft patch is designed to be flexible and to conform to various body flexures.

Given the limitations imposed on transdermal systemic drug delivery by the barrier properties of the stratum corneum, new technologies have attempted to completely bypass this obstacle by either the creation of a physical conduit (microneedles) or direct powder delivery via compressed gas. The Alza Corporation technology (MacrofluxTM) comprises a patch system that contains a microprojection array designed to create superficial microchannels across the stratum corneum (67). When used in conjunction with their electrotransport system, the Macroflux system provides controlled *in vivo* delivery of therapeutic doses of antisense oligonucleotide, human growth hormone, and insulin. Similarly, the Radeon Inc. system consists of microfabricated microneedles that are 150 μm in length and may be either solid or hollow (68). The Radeon system was effective in enhancing by several orders of magnitude the human epidermal permeability of calcein and bovine serum albumin (Fig. 7) (69).

Transdermal powder delivery uses a supersonic flow of helium to accelerate drug particles to velocities sufficiently high to penetrate the stratum corneum (70). The needle-free injection system is capable of painlessly delivering drugs and vaccines in powder form into the skin. The amount of drug delivered is related to particle size, dose level, and the device operating power. Recent data demonstrated that the powder delivery system was capable of delivering salmon calcitonin across rabbit skin in a dose-dependent (but nonlinear) manner (71). A similar system (the HeliosTM gun system) was used to determine the effect of the dose regimen of a model drug

incorporated into poly-*L*-lactic acid microspheres of varying particle size (72). It was concluded that more frequent applications that contain lower amounts of the model drug generated a superior plasma profile than larger drug loadings at less frequent dosage intervals.

RECENT REGULATORY INITIATIVES

SUPAC-SS—Drug Release from Semisolid Formulations

Determination of the ability of a semisolid formulation to release a drug, the pattern of release and the rate at which this release occurs are important aspects of formulation development and optimization. However, it is also important to appreciate that the data obtained should not be overinterpreted. Release studies normally involve the measurement of drug diffusion out of a mass of formulation into a receiving medium that is separated from the formulation by a synthetic membrane (73). A detailed analysis of the data obtained in this type of experiment can be expected to generate invaluable data concerning the physical state of the drug in the formulation. For example, an examination of the early models and their refined updates derived to describe drug release from semisolids reveals that release patterns are different depending on whether the drug is present as a solution or suspension within the formulation (74). These subtle differences, together with differences in the rate of release, may be used to determine such parameters as drug diffusivity within the matrix of a formulation, the particle size of suspended drug, and the absolute solubility of a drug within a complex formulation (Fig. 8) (75, 76). Although it is generally agreed that drug release rate data cannot be used to predict skin permeation or bioavailability, release rate determinations are important for purposes other than formulation development and characterization.

The Food and Drug Administration (FDA) has issued a guidance document (SUPAC-SS Nonsterile Semisolid Dosage Forms, US Department of Health and Human Services, Food and Drug Administration, Center for Drug Evaluation and Research, May 1997) that recommends the use of *in vitro* drug release testing in the scale-up and postapproval changes for semisolids (SUPAC-SS). The FDA intends to promote the use of this test as a quality assurance tool to monitor minor differences in formulation composition or changes in manufacturing sites, but not at present as a routine batch-to-batch quality control test. Thus, the FDA is suggesting *in vitro* release rate data for Level 2 and Level 3 changes in formulation components

Fig. 7 Permeability of *in vitro* human epidermis to bovine serum albumin (BSA) and calcein. In the absence of microneedles, permeation was below the limit of detection. (Plotted from data given in Ref. 69.)

Fig. 8 Illustration of the use of release rates from semisolid preparations to determine drug solubility within a formulation. Data show the release rates of benzocaine from propylene glycol/water gels as a function of drug concentration in the formulation. (Redrawn from Ref. 75.)

and composition but such data are not required for a Level 1 change. In the former, the *in vitro* release rate of the new or modified formulation should be compared to a recent batch of the original formulation, and the 90% confidence limit should fall within the limits of 75–133%. Similarly, *in vitro* release testing is suggested for Level 2 changes in manufacturing equipment, processes, and scale-up, and Level 3 changes in manufacturing site. Recently, the use of *in vitro* testing as a quality assurance tool has been questioned, especially in the case of a hydrophilic formulation that contains the highly water soluble drug ammonium lactate (77). The method was found not to be specific enough to differentiate between small differences in drug loading or minor compositional and processing changes.

Bioequivalence of Dermatological Formulations

In practice, bioequivalence of dermatological dosage forms creates particular difficulties because it is often difficult to determine the very low blood levels of specific drugs following dermal application. The FDA has pioneered the use of alternative methods of evaluation including the investigation of dermatopharmacokinetics using the tape-stripping method. The use of *in vivo* skin stripping in dermatopharmacokinetic evaluation was the subject of an AAPS/FDA workshop concerning the bioequivalence of topical dermatological dosage forms

(Bethesda, MD, September, 1996). Although opinion was somewhat divided, it was concluded that stratum corneum tape stripping “may provide meaningful information for comparative evaluation of topical dosage forms” (78). Furthermore, it was established that a combination of dermatopharmacokinetic and pharmacodynamic data could provide sufficient proof of bioequivalence “in lieu of clinical trials.” However, much remains to be validated in skin stripping protocols. The *in vivo* tape stripping technique is based on the dermal reservoir principle developed by Rogier et al. (79). It is hypothesized that if a compound is applied to the skin for a limited time (for example 0.5 h) and then removed, the amount of drug in the upper layers of the stratum corneum will be predictive of the overall bioavailability of the compound. It follows that determination of the stratum corneum content of a permeating material following a short-term application will predict *in vivo* bioavailability from a corresponding administration protocol. Data obtained in studies of this type have shown reasonable predictability for several compounds.

An outline protocol for skin-stripping bioequivalence studies has been suggested (78). The basic protocol has two phases: uptake and elimination.

Uptake

1. Test and reference drug products are applied concurrently at multiple sites.
2. After exposure for a suitable time (determined by a pilot study), excess drug is removed by wiping three times with tissue or cotton swab.
3. The adhesive tape is applied with uniform pressure. The first strip is discarded (skin surface material). This is repeated if necessary to remove excess surface material.
4. Collect nine successive tape strips from the same site. If necessary collect more than nine strips.
5. Repeat the procedure for each site at designated time intervals.
6. Extract the drug from the combined tape strips for each time point and site and determine the content of drug using an appropriate validated analytical method.
7. Express the data as amount of drug per cm^2 of tape.

Elimination

1. Repeat steps 1, 2, and 3 “Uptake” phase.
2. After a predetermined time interval (e.g., 1, 3, 5, and 21 h postdrug removal) perform steps 4 through 7 of “Uptake” phase.

Fig. 9 Idealized dermatopharmacokinetic profile for a topically applied compound illustrating uptake and elimination phases. The amount of drug in the stratum corneum is determined by summing the total amount removed by tape stripping at each time interval.

The results are then expressed as the amount of drug recovered from the tape strips against time. Uptake and elimination phases are observed (Fig. 9) and bioavailability may be predicted from the area under the curve. There are several sources of variability in such studies, all of which must be considered in standard operating procedures. The major causes of concern in variability are:

1. drug application procedure
2. type of tape
3. size of tape
4. pressure applied by investigator
5. duration of application of pressure
6. drug removal procedure
7. drug extraction procedure
8. analytical methodology
9. temperature
10. relative humidity
11. skin type
12. skin surface uniformity

Other concerns have been expressed (80). These include the observation that vehicle components of the products to be evaluated may have different effects on the adhesive properties of the tape. In addition, it is important to appreciate that because the dermatopharmacokinetic bioequivalence studies will most likely be carried out on normal disease-free human volunteers, the generated data may show little resemblance to the actual drug distribution

within the stratum corneum of patients. Nonetheless, following further validation, the technique will have several advantages. For example, basic pharmacokinetic parameters, such as AUC, C_{max} , T_{max} , and half-life, may be approximated from the data obtained. In addition, the approach could be applicable to all types of topical preparation.

Recently, Pershing (81) reviewed much of the extensive validation of typical in vivo skin stripping techniques. Such variables as the test region anatomical site, individual investigator technique, adhesive systems and product dose, application, and removal techniques were discussed. It was concluded that "careful validation of adequate removal of residual applied product, the collection of skin stripping samples and a sensitive analytical assay were critical to the appropriate interpretation of the results" (81). Further details of the dermatological drug product bioequivalence guidelines, including the proposed protocol, may be obtained from the FDA draft guidance document (Topical Dermatological Drug Product NDAs and ANDAs—In Vivo Bioavailability, Bioequivalence, In Vitro Release, and Associated Studies, U.S. Department of Health and Human Services, Food and Drug Administration, Center for Drug Evaluation and Research, June 1998).

CONCLUDING REMARKS

The title of this article, *Drug Delivery—Topical and Transdermal Routes*, describes a field of pharmaceutical sciences that has expanded rapidly over the past 30 years. For example, it was only a few years ago that noninvasive transcutaneous immunization was only available on the 'Starship Enterprise.' Now the technology is available (82). To include all recent developments would require much more space than is feasible within the scope of this encyclopedia. Quite selfishly, therefore, I have elected to cover those subjects in which *I am* most interested. In partial mitigation, I have provided a reasonably complete bibliography and have attempted to point the reader who wishes to explore in more depth subjects not covered herein toward the most relevant recent references. Topical drug delivery, for either dermatological or transdermal therapy, is a fascinating subject, made more so by the nature of the skin. The more we understand the molecular biology of this unique organ, the more able we will be to fix it when it goes wrong. Similarly, a deeper understanding of skin barrier morphology will allow us to develop strategies to modify its permeation properties.

These are fundamental issues and improvement of our knowledge will increase our capabilities as drug delivery scientists. In this section, I have attempted to outline recent developments in the development of the stratum corneum and some of the methods used to modify the inherent barrier properties of this unique membrane. Some strategies for reducing adverse dermatological events associated with topical therapy have been discussed. Novel delivery systems were outlined and recent regulatory initiatives, which are planned to make life easier for the pharmaceutical industry, were described. I hope that my comments will provide the drug delivery specialist with some insights borne of experience and the experienced topical formulator with some alternative concepts in the field of dermatological and transdermal product development.

DRUG DELIVERY—RECTAL ROUTE

J. Howard Rytting

Joseph A. Fix

Yamanouchi Pharma Technologies, Inc., Palo Alto, California, U.S.A.

INTRODUCTION

Drug Delivery Routes

Although administration via the peroral route is the most commonly targeted goal of new drug and dosage form research and development, oral administration is not always feasible or desirable. The potential for oral dosage form development is severely limited for active agents that are poorly absorbed in the upper gastrointestinal (GI) tract and unstable to proteolytic enzymes. Some agents cause local stomach or upper GI irritation or require doses in excess of 500 mg. Certain patient populations, notably children, the elderly, and those with swallowing problems, are often difficult to treat with oral tablets and capsules. Additionally, treatment of some diseases is best achieved by direct administration near the affected area, particularly with diseases involving ophthalmic, otic, dermal, oral cavity, and anorectal tissues. Although oral administration can be used for drugs targeted for some of these diseased tissues, exposure of the entire body compartment to the administered drug is inefficient and can lead to undesired adverse effects. Rectal drug administration is amenable, however, to both local and systemic drug delivery. It has been effectively utilized to treat local diseases of the anorectal area as well as to deliver drugs systemically as an alternative to oral administration. In this article, factors influencing the utilization of rectal drug administration as well as the advantages and disadvantages of this approach, are discussed. A survey of the pharmaceutical literature for the last 5–7 years suggests that this administration route has not received a great deal of attention in the pharmaceutical community. Relatively few articles have appeared in the literature (1–4) and new products have not captured a significant segment of the pharmaceutical market. Although rectal drug administration is unlikely to ever become a commonly accepted route of administration, the utilization of this technology for particular applications and therapeutic problems offers an alternative delivery route which can be successfully applied in drug therapy.

Rectal Formulations Available

Solid suppositories

Solid suppositories are the most common dosage form used for rectal drug administration and represent greater than 98% of all rectal dosage forms. Typically, these are torpedo-shaped dosage forms composed of fatty bases (low-melting) or water-soluble bases (dissolving) which vary in weight from 1 g (children) to 2.5 g (adult). The composition is largely dictated by the physicochemical properties of the drug and the desired drug release profile. Lipophilic drugs are usually incorporated into water-soluble bases while hydrophilic drugs are formulated into the fatty base suppositories. Theoretically, this method maximizes removal of the drug from the suppository base to the immediate environment of the rectal cavity or lower colon. For suppositories made from fatty bases, melting should occur rapidly near body temperature (37°C). Ideally the resultant melt would readily flow to provide thin, broad coverage of the rectal tissue, thereby minimizing lag time effects due to slow release of the drug from the suppository base. Water-soluble suppositories should likewise readily dissolve at 37°C to facilitate drug release and subsequent absorption. With both fatty-base and water-soluble suppositories, the potential effects of incorporated drug on melting or dissolution properties need to be evaluated. Examples of fatty bases and water-soluble bases suitable for suppository formulations are shown in Table 1. Although not comprehensive, the list shows the variety of bases from which a formulator may choose.

Solutions

Solutions, suspensions, or retention enemas represent rectal dosage forms with very limited application, largely due to inconvenience of use and poor patient compliance. In many cases, these formulations are utilized to administer contrast media and imaging agents for lower GI roentgenography. Although drug absorption from solutions has been shown to exceed that from solid suppositories in some cases (5), this particular administration route is only

Table 1 Suppository bases

Vehicle	Melting range (°C)	Solidification point (°C)
Fatty bases		
Witepsol	32–44	27–38
Cocoa butter	30–35	24
Hard butters	36–45	32–40
Estarinum	29–50	26–40
Suppocire	35–45	30–37
Agrasup A;H	35–40	—
Water soluble		
Myrj 51	39–42	39
PEG ^a	38–49	38–42
Tween 61	35–49	—

^aPolyethylene glycol.

(From *Modern Pharmaceutics*; Banker, G. S., Rhodes, C.T., Eds.; Marcel Dekker, Inc.: New York, Basel 1979.)

infrequently employed and will not be discussed here in detail. Recent studies utilizing liquid formulations that gel at body temperature are discussed in the Gels/foams/ointments section.

Gels/foams/ointments

The use of gels, foams or ointments for rectal administration can afford advantages over liquid formulations because retention of the dosage form in the rectal cavity reduces patient compliance problems. Drug release with semisolid dosage forms is usually limited to local indications such as hemorrhoids and lower bowel inflammation (proctitis). Drug release and subsequent pharmacologic action is usually faster with semisolid formulations than with solid suppositories since a lag time is not required for melting or dissolution.

Miyazaki et al. (1) investigated thermoreversible gels formed by a xyloglucan polysaccharide derived from tamarind seed. Liquids containing 1–2% xyloglucan formed gels over a temperature range of 27–32°C. The gelling temperature decreased with increasing xyloglucan concentration. In vitro release profiles for indomethacin and diltiazem were characterized as a square-root of time function with diffusion coefficients increasing with temperature increases from 10 to 37°C. The slower in vitro indomethacin release from gels was confirmed in vivo where broader absorption peaks and longer residence times were noted. There were, however, no significant differences in bioavailability between the thermal gelling formulations and conventional indomethacin suppositories.

Ryu et al. (2) examined mucoadhesive liquid suppositories that combined bioadhesive properties with

thermal gelling polymers. Hydroxypropylcellulose, polyvinylpyrrolidone, carbopol, polycarbophil and sodium alginate were used as bioadhesive polymers in thermal gelling polymers comprised of poloxamer 407 and poloxamer 188. Gellation temperatures between 30 and 36°C were obtained with mucoadhesive forces ranging from 430 to 5800 dyne/cm². With propranolol as a model compound, bioavailability increased as the mucoadhesive force increased and dosage form migration distance decreased. There was, however, no direct relationship between bioavailability and gellation temperature. Sodium alginate and polycarbophil afforded the greatest mucoadhesive forces and most significant improvements in propranolol bioavailability. Sodium alginate was also free of any quantifiable adverse effects on rectal tissue. The studies suggest that reduced formulation migration as a function of mucoadhesive potential was the primary causative factor for the improved bioavailability of propranolol.

Watanabe et al. (4) have reported improved rectal absorption with reduced mucosal irritation utilizing rectal gels comprising water-soluble dietary fibers, xanthan gum and locust bean gum. Absorption of buprenorphine was more rapid than that observed from polyethylene gels with comparable extents of bioavailability. Mean residence times increased with increasing gum concentrations. Most importantly, the degree of mucosal irritation from these dietary fiber gels was significantly less than that observed with polyethylene based suppositories.

Controlled-release formulations

Controlled-release formulations are designed to release the active agent in a sustained and controlled fashion. They have been the subject of considerable research but have yet to make a significant impact. Hydrogels have been shown in human clinical studies to provide an acceptable polymeric system for rate-controlled delivery of antipyrine and theophylline (6). Rate-controlled osmotic delivery systems have also proven useful in clinical studies in effecting systemic drug delivery comparable to that of intravenous administration for well absorbed drugs (7). Since the total acceptable size of a rectal formulation significantly exceeds the size possible for oral formulations, rectal administration for the purposes of controlled-release offers a significant advantage. A major limiting factor is, however, the need to incorporate controlling agents designed to regulate drug release which would significantly increase the total size of the dosage form. Since adult rectal dosage forms are acceptable up to 2.5 g, the total drug load which can be formulated in a rectal controlled-release formulation can be 2–3 times that possible in an oral formulation. For some therapeutic agents, this higher drug load can offer an advantage which

is not achievable via the oral route. Development and marketing of rectal controlled-release formulations will, however, still be disadvantaged because of the perceived reluctance of patients to employ this route and problems of poor patient compliance.

Marketed drugs and therapeutic classes

Only a limited number of therapeutic agents are currently marketed in the United States as rectal dosage forms. A survey of the 1994 American Hospital Formulary Service shows that 19 agents are sold for systemic therapeutic indications (Table 2) and 15 agents for local GI applications (Table 3), including imaging agents for diagnostic purposes. Many products for local GI application are over-the-counter (OTC) products for treatment of local inflammatory reactions and hemorrhoids. As is readily evident from the limited number of therapeutic agents available for rectal administration, this dosing route does not represent a major share of the physician's choices for drug therapy.

Worldwide market

In certain areas of the world, particularly some European countries and Japan, rectal dosage forms are somewhat more accepted by the patient population and, hence, development of rectal dosage forms has surpassed that in the United States. According to a survey in 1970, approximately 7.5% of all prescriptions in France were formulations intended for rectal administration (8). Even though a few countries may find rectal dosage forms more acceptable, these still represent a small area of the world-wide market share which can be assigned to rectal drug therapy.

PHYSIOLOGIC AND PHARMACEUTICAL ISSUES RELEVANT TO RECTAL DRUG DELIVERY

Physiology and Biochemistry of Rectal Tissues

Anatomical considerations

Unlike the small intestine and upper colon, the vasculature draining the rectal cavity does not totally direct the blood supply to the liver (9). The lower and middle hemorrhoidal veins of the rectum bypass, at least partially, the portal circulation during their first pass into the general circulation, allowing absorbed drug to exert systemic effects prior to possible metabolism and excretion via hepatic mechanisms. Lignocaine, propranolol, and salicylamide have been shown in clinical studies to attain greater systemic bioavailability when administered rectally than

Table 2 Rectal dosage forms marketed in the United States for systemic indications

Therapeutic category and drug	Drug load, solid ^a (mg)
Antihistamine	
Promethazine	12.5–50
Antimigraine	
Ergotamine	2

when given orally (10). The rectal cavity is also drained by extensive lymphatic circulation which facilitates absorption and systemic exposure of absorbed drugs (11).

Although extensive villi and microvilli are not present in the rectum and colon tissue, sufficient surface area is present to allow absorption of readily permeable drugs. The lack of motility in the rectum and colon, as opposed to extensive motility in the small intestine, provides an additional advantage in terms of maintaining maximum concentration gradients at the absorptive surface. Together with a limited fluid volume in the lower colon, typically 2–3 ml of inert mucous fluid in the absence of fecal material, the static environment of the rectum and lower colon provides an area for maintaining significantly higher

Table 3 Rectal dosage forms marketed in the United States for gastrointestinal indications

Therapeutic category and drug	Drug load	Physical form
Laxatives		
Senna	30 mg	Solid
Glycerin	4 ml	Solid or liquid
Mineral oil	—	Liquid
Potassium bitartrate		Solid
Dibasic sodium phosphate	—	Solution
Docusate sodium	—	Suspension
Hemorrhoids		
Hydrocortisone	100 mg	Suspension or cream
Hydrocortisone acetate or butyrate	—	Aerosol, foam, and suspension
Dibucaine	—	Ointment
Proxamine	1%	Ointment
Proctitis, colitis		
Belladonna	16.2 mg	Solid
Mesalamine	500 mg	Solid
Enteropathogenic diarrhea		
Neomycin	—	Retention enema
Contrast imaging agents		
Barium sulfate	5–70% (w/w)	Suspension
Diatrizoate	60–66%	Solution

drug concentrations than is readily achievable in the small intestine. On the negative side regarding potential for drug absorption, the intercellular junctional complexes are tighter in colon and rectum than in small intestine (12) which may reduce opportunities for small, water-soluble drugs to permeate intercellular spaces and gain access to the systemic circulation without passing through cellular membranes.

Biochemistry

Cellular metabolism of drugs, as they pass through the mucosal barrier of the rectum or colon, can be expected to be similar to that seen in the small intestine since the basic intracellular metabolic machinery is common to epithelial cells. The major difference relative to drug metabolism occurs in the enzymes to which drugs are exposed in the intestinal lumen and on the apical membranes of the epithelial cell layer. Since the colon and rectum do not serve digestive functions, the luminal enzymes, which are actively secreted in the upper small intestine, are not present to any significant extent. As such, proteolytically labile drugs such as peptides and proteins should exhibit greater stability if released in the rectum or lower colon. Saffran et al. have shown that vasopressin, a peptide subject to proteolytic hydrolysis, is more active when administered by the rectal route than by oral administration

(13). Significant rectal absorption of growth hormone (14) and insulin (15) have also been demonstrated with the help of absorption enhancing agents. The apical membranes of the small intestine epithelial cell layer express high levels of membrane-associated or membrane-bound enzymes, such as peptidases and saccharidases, which are not present in high amounts on the apical surfaces of epithelial cells in the rectal cavity. This absence of membrane surface metabolic potential affords advantages when delivering drugs susceptible to enzymatic degradation. These membrane-associated enzymes are, however, linked to direct transport carriers for specific nutrients, notably amino acids and sugars. Carriers for many of the vitamins are also present in small intestinal tissue. The relative absence of these transport mechanisms in colon and rectal tissue (16) eliminates this mechanism of absorption as a viable route for rectal drug delivery. Since most of these amino acid, saccharide, and vitamin carriers have relatively specific structure and transport requirements, the absence of these systems in colon or rectal tissue affects only drug candidates with significant structural similarity to natural substrates.

The pH of the rectal compartment is essentially neutral, ranging from 7 to 8, with minimal buffering capacity as compared to the small intestinal milieu. Suppositories or solutions formulated to maintain a specific pH in order to

optimize drug absorption typically will function at that pH following administration. This can be a significant advantage with drugs whose permeation properties are optimized near neutrality. It should be kept in mind, however, that the controlling pH at the epithelial membrane surface, which is under the overlying mucous layer, is still in the range of pH 6.0–6.5 as it is throughout the small and large intestine. Therefore, even though luminal pH may favor drug absorption and diffusion from the lumen to the cell barrier, the effective pH at the cellular barrier is not drastically different from other regions of the intestinal tract. In this sense, perceived pH advantages of rectal drug administration may be obviated by the basic surface pH which is characteristic of mucosal tissue.

Model Systems and Techniques

Whole animal models

Preliminary *in vivo* evaluation of the rectal absorption potential of drug candidates is most easily achieved in a rat model (17, 18). Animals can be maintained at surgical plane anesthesia for 120–180 min, and drug solutions or suspensions can be directly instilled into the rectal cavity. Utilizing a slight elevation above horizontal, instillation of approximately 0.25 ml is readily achieved in rats without loss of fluid from the rectal compartment. Purse-string sutures or moderate pressure clamps can also be used to prevent leakage of administered solutions from the rectal cavity. In most cases, it is advisable to fast animals for 12–16 h prior to study to void the colon and rectal cavity of fecal material which may interfere with administration of the solution or absorption of the drug itself. Microsuppositories can also be evaluated in the rat model by utilizing specially designed molds to prepare small dosage forms, but care must be taken to guarantee drug content uniformity in these small devices. Additionally, since drug absorption can be influenced by the choice of suppository base, this must be taken into consideration in any analysis of the rectal absorption potential of a drug candidate.

Rabbits have been another common animal model utilized for examining rectal drug absorption. Constraints with using this animal model are similar to those encountered with the rat model, although there is more latitude concerning the volume (solid or liquid) of the dosage form which can be tested. A possible drawback to the rabbit model is evidence suggesting that the rabbit colon is somewhat more “leaky” than the colon in other species. In this regard, the rabbit model may overestimate the extent of drug absorption achievable for small, water-soluble compounds which utilize intercellular transport pathways via water flux.

For evaluation of dosage forms designed and formulated for human use, the Beagle dog presents an ideal animal model (18, 19). Solid suppositories (up to 2.5 g total weight) or microenemas (up to 5 ml volume) can be readily tested in Beagles without concern for loss of dosing vehicle from the rectal compartment. Since the physical dimensions of the dog rectum approximates those of the human rectum, variables such as spreading of suppository bases can be reasonably well evaluated. The dog is obviously a convenient model for blood sampling and pharmacokinetics and is, therefore, well suited for the evaluation of rectal dosage forms. Studies from the author’s laboratories and others have shown that dosage-form performance criteria generated in Beagle dog models are accurate predictors of performance in human clinical trials (20).

In vitro models

For assessing the absorption potential of specific drug candidates or conducting studies evaluating correlations between drug structure and transport, *in vitro* models may provide the best approach. Both the tissue-diffusion cell systems and cultured colon cell lines have proved to be particularly useful.

Numerous investigators have employed diffusion chambers of various designs (e.g., Ussing chambers, Sweetana–Grass diffusion cells) to evaluate the permeation properties of drug candidates (21, 22). These systems offer a distinct advantage that drug solutions may be added to the donor compartment under a variety of conditions (e.g., varying concentrations, pH, excipients). Samples are withdrawn periodically from a receiver compartment and analyzed for drug and metabolite content to obtain a true measure of permeation across the cellular barrier. In establishing procedures for these diffusion cell studies, the underlying muscle layer can be teased away and only the intact mucosal cell layer mounted in the diffusion chamber. Since the underlying muscle layer is not a barrier encountered under normal physiologic conditions, this method more accurately reflects the true cellular barrier to drug transport. It should be noted that, in many cases, any mucus layer normally overlying the mucosal cell layer may be disrupted and removed by the physical manipulations and tissue washing procedures normally employed in the experimental design. Therefore, for drugs where diffusion through the mucus layer may represent the rate-limiting step, this model may overestimate drug permeation unless great care is taken to maintain the mucus layer. Conversely, the use of mucolytic agents can be employed to ensure a mucus-free cell layer if true cellular drug permeability is to be determined. Work in the author’s laboratories has demonstrated that the Sweetana–Grass diffusion cell model with muscle-free mucosal layers is

reasonably resistant to experimental conditions. The pH can be varied between 5 and 8 without significant damage to the mucosal layer. Additionally, excipients such as DMSO or ethanol, can be utilized up to 10% (v/v) in order to improve solubility of drugs whose absorption may be limited by poor aqueous solubility. Finally, our experiments have shown that muscle-free mucosal strips can be maintained with good viability for up to 120 min at 37°C, although this should be experimentally determined in each laboratory using this model to ensure that tissue damage is not affecting the measured drug transport values. Typically, standard metabolic viability assays and microscopy are suitable for confirming tissue viability.

Another *in vitro* model that has experienced significant growth in utilization in drug transport studies and which may provide useful information relative to rectal or colonic drug absorption is cultured cell monolayers. HT-29 and Caco-2 cells are two cell lines commonly employed for such studies (20, 25). Both are human colon-cancer cell lines which can be grown on membrane filters and readily form confluent monolayers with intact tight junctional complexes (typically $>250 \Omega \text{ cm}^2$). They can be used in experimental designs similar to the diffusion cell models. These cells are non-mucus secreting cell populations which resemble fetal small intestine in many of their metabolic properties. Although these models are useful for quantifying drug transport across colon cell lines, certain limitations must be kept in mind. First, aqueous pathways in these confluent monolayers are significantly reduced compared to the *in vivo* situation. In other words, the intercellular pathway, as monitored by electrical resistance, is less “leaky” than that encountered in normal colon or rectal tissue and drug transport studies may underestimate the absorption of drugs which utilize the paracellular pathway. Second, there is evidence to suggest that some of the carrier systems present in small intestinal epithelial cells (e.g., vitamins, dipeptides) are also present to some extent in these cell lines (26, 27) which may provide misleading information on the rectal absorption potential for compounds which utilize these carriers. Finally, these are transformed cells which may or may not present metabolic barriers comparable to that seen in normal colon or rectal tissue. Care must be taken in interpreting data from transport studies which show parent drug metabolism during the absorptive phase since this may or may not also occur *in vivo*.

Advantages over Oral Systems

Improved enzymatic drug stability

It is well known that the oral delivery of many drugs, particularly peptides and proteins, is limited due to poor

absorption and/or stability in the stomach and upper intestinal tract. Many proteolytic and other enzymes in the stomach and small intestine result in drug degradation which prevents effective absorption following oral administration. As discussed above, degradative enzymes are present to a much lesser degree in the rectum and therefore many drugs that cannot be administered effectively orally can be administered rectally without as much enzymatically catalyzed degradation. Examples include vasopressin (13), growth hormone (14), and insulin (15). It has been found necessary to include absorption enhancing agents for growth hormone and insulin.

Partial avoidance of hepatic first pass

The rectum is extensively supplied with blood from the various rectal arteries. It is drained by at least three veins (28) and drug absorption primarily occurs through this venous network. Although there is substantial intermingling of these veins due to several anastomoses, it is usually reported that the inferior and middle rectal veins drain into the inferior vena cava. This allows drugs absorbed by this route to partially bypass the portal system and the associated first-pass metabolism in the liver. As an example of this effect, de Boer and Breimer (10) have shown that the systemic bioavailability in humans for lignocaine is about twice that observed following oral administration. It has been suggested that about half of rectally administered drug avoids hepatic presystemic metabolism. Clinical studies have also shown higher systemic bioavailabilities for propranolol and salicylamide when administered rectally compared with oral administration (10). Studies in rats suggest that first pass metabolism is almost totally avoided by rectal administration. For example, the bioavailability of nitroglycerin in rats following unrestricted rectal instillation was about 27% compared to 2% from oral dosing. When the length of rectal tissue exposed to the drug was restricted to 2 cm from the anus, the bioavailability increased to about 90% (29).

The fact that rectal administration in humans only partially avoids delivery of the drug to the portal system has been suggested as an advantage of rectal administration of insulin over parenteral administration (30). Delivery of insulin to the portal blood system is suggested to be more physiological than delivery to the peripheral cells from subcutaneous injections.

Higher drug load

In general, oral administration in a single tablet is limited to about 1 g. Typically, suppositories intended for adults can be as large as 2.5 g. This should allow for two to three

times higher drug loads to be administered, depending on the amounts of other excipients necessary in the formulation of the suppository.

Lymphatic delivery

Some studies have indicated that significant amounts of some drugs are transported through the lymphatic systems following rectal administration. For example, Caldwell et al. (11) have examined the importance of lymphatic transport of water-soluble drugs following rectal administration in the presence of salicylate-type adsorption enhancers. They observed that following i.v. injection to the rat, the concentration of phenol red in the plasma and the lymph (collected from the thoracic duct) were similar. They further found that concentration of phenol red in the lymph after rectal administration to rats via cannulated thoracic ducts was more than 100 times greater than corresponding plasma concentrations when 5-methoxysalicylate was used as an adjuvant. Rectal administration of phenol red in the presence of 5-methoxysalicylate to rats with intact thoracic ducts produced plasma levels of phenol red which were about fivefold greater than those found in the rats in which lymphatic drainage had been diverted. As shown in Fig. 1, insulin was also transported primarily through the lymphatic system to the general circulation. However, theophylline exhibited much lower lymphatic transport.

Constant and static environment

Compared to the oral route of administration, the rectal route provides a much more constant environment for the drug as it is absorbed. An orally administered drug must usually pass through a series of diverse environments prior to absorption. This includes transit through the stomach and the small intestine and perhaps to the large intestine and colon, depending on the drug and the absorption site. The pH and absorptive sites in the GI tract change significantly as the drug traverses it. This can lead to a more complicated set of conditions which influence absorption compared to the rectum which is a short part of the GI tract with relatively constant absorption characteristics.

Patients with swallowing difficulty

For a number of patients, especially children and elderly, problems associated with swallowing and nausea when taking oral medication can be largely obviated by rectal administration. Patients with gastrointestinal disorders or after surgery often have difficulties taking drugs by mouth. Rectal administration may be a good alternative to oral administration in these types of situations.

Fig. 1 Concentration of insulin in the plasma and lymph of rats following intramuscular administration of 0.8 IU/body insulin (●), rectal administration of 2.0 IU/body insulin in the presence of 10 mg/body 5-methoxysalicylate and intact thoracic duct (▲), and rectal administration of 2.0 IU/body insulin in the presence of 10 mg/body 5-methoxysalicylate with the thoracic duct cannulated for collection of lymph (○). The error bars represent standard deviations with $n = 6$. (From Ref. 11.)

Avoidance of overdosing

For some patients and with certain drugs, such as certain sedatives, oral administration may raise a concern with respect to the possibility of severe accidental or intentional overdosing. This danger is practically eliminated by rectal administration. Whereas it is relatively easy for a patient to swallow a number of tablets, it is much more difficult to administer numerous suppositories rectally at the same time. Thus rectal administration may be indicated for patients for whom overdosing is a significant concern.

Disadvantages Compared to Oral Systems

Patient acceptance and compliance

In some cultures, such as in the United States, there is a reluctance by many to consider rectal administration. This has resulted in a tendency by pharmaceutical marketing groups to avoid rectal dosage forms, except for the most obvious indications and situations where other dosage forms have substantial disadvantages. Frequently, it is inconvenient to receive or administer a suppository or other rectal dosage form, thereby reducing patient compliance. Thus, the need must be great in most cases for rectal administration to be seriously considered.

Potential for nonspecific drug loss

There are at least two common problems that can lead to drug loss following rectal administration. First, for effective absorption, the dosage form must be retained in the rectum. Thus if the dosage form or parts thereof are lost prematurely from the rectum, drug absorption will be substantially reduced. A study with children showed that when thiopentone suppositories were voided within 40 min, an effective plasma level was maintained for less than 2 h, whereas when the suppositories were retained, an effective level was maintained for about 24 h.

Second, there is the possibility that the drug or some important excipients may interact with constituents of fecal matter or material fluid present in the rectum. This may reduce the drug absorption and diminish effectiveness.

Limited fluid in the rectum

The amount of liquid in the rectum has been reported to be about 3 ml. This is small compared to the volume of fluid available throughout the GI tract when a drug is administered orally. Such a small volume of fluid can limit dissolution of drugs, particularly those with low aqueous solubility. It also may be a constraint to the rapid dissolution and release of compounds from water-soluble vehicles where dissolution of the vehicle is considered to be the rate-determining step in drug release from the vehicle.

Formulation

There are a number of formulation variables and considerations that can lead to difficulties in rectal drug absorption, including the melting and liquefaction characteristics of the vehicle. The solubility of the drug in the vehicle, the particle size of the drug, the vehicle spreading capacity, the viscosity of vehicle and excipients at rectal temperature, and possible retention of the drug by excipients, all can affect the rate of release and consequent drug absorption. Furthermore, the pK_a of the drug, the pH of the rectal fluids, the presence of buffers, and the buffer capacity of the rectal fluid as well as the partition coefficient of the drug influence drug absorption and must be considered in the formulation of a suppository or other rectal dosage form. Storage temperature, time, and conditions can have a profound effect on both the stability and release characteristics of a drug from a rectal dosage form. Each of these considerations lead to potential difficulties in the formulation, manufacture and distribution of rectal dosage forms.

Expense

Suppositories and other rectal dosage forms are more expensive to prepare and dispense than simple tablets. Therefore, unless there is a significant need and advantage by utilizing a rectal dosage form, suppositories are not likely to be used. Recently, techniques have been developed to prepare suppositories more efficiently which could lead to lower manufacturing costs.

Drug Classes Useful for Rectal Administration

Drugs that are currently marketed in the United States for rectal delivery are shown in Tables 2 and 3. In addition to drugs intended for local effects, many other types can be administered rectally for systemic activity, such as drugs with high hepatic first-pass extraction, drugs for which lymphatic absorption is important, and compounds requiring a relatively high therapeutic dose. Generally, drugs requiring significantly more than 500 mg per tablet are not easily taken orally and in some cases may be candidates for rectal delivery.

Although products are not currently marketed containing proteins and peptides, the literature contains several examples of rectal absorption of peptides and proteins. Typically proteins and peptides require some type of penetration-enhancing adjuvant in the formulation to facilitate absorption. Examples of peptides and proteins that have shown significant rectal absorption include: insulin, lysozyme, calcitonin analogs, phenylalanine and di-, tri-, and tetraphenylalanine, as well as gastrin, pentagastrin and tetragastrin (31).

ABSORPTION CHARACTERISTICS AND REGULATION OF DRUG ABSORPTION

Control or Modification of Rectal Drug Absorption

pH partition

The mechanism for absorption from the rectum appears to be similar to that observed for the rest of the GI tract, that is, passive diffusion. Drugs are best absorbed through the rectal mucosa in their un-ionized or neutral form. Drugs with high partition coefficients (more lipophilic) tend to be better absorbed. There are, however, conflicting reports in the literature with some suggesting that simultaneous absorption of ionic species is possible. That is particularly true for relatively small molecules. If the drug can exist in the unionized state at physiological pH, other factors being equal, absorption is improved.

Solubility

As was pointed out earlier, the volume of fluid in the rectum is very small. In most cases, it is believed that the drug should be dissolved in the rectal fluid prior to absorption. This requires that drugs have a reasonably high solubility to be efficiently absorbed from the rectum. Voigt and Falk (32) reported a direct relationship between water solubility and release rate for 35 different compounds. Generally, when a compound can be presented in relatively low solubility form (e.g., neutral acid) or as a more water-soluble form (e.g., the sodium salt), the higher the solubility and consequently the higher the dissolution rate in the rectal fluid, the better is absorption. This factor has to be balanced with the fact that an unionized species tends to pass through the rectal mucosa more readily.

Drug solubility also affects the choice of suppository base or other vehicle. Generally, the drug should have little tendency to remain in the vehicle upon melting or dissolution. Therefore, it is usually suggested that water soluble drugs are best delivered from fatty vehicles and that more lipophilic compounds from water-soluble vehicles.

Molecular size

The smaller the drug molecule, the more readily it can be absorbed. For larger molecules, some type of facilitated transport or the use of penetration enhancers have been found to increase drug absorption from the rectum as well as from other delivery routes.

Charge

Charged molecules have been found to pass through the rectal mucosa less effectively than neutral molecules in most cases. This can sometimes be overcome by modifying the pH or allowing the charged species to interact with another molecule or ion that helps neutralize the charge. Ion pairs, for example, hold some promise for overcoming the drawbacks of charged species. From a solubility point of view, charged species are generally preferred. Often a balance between high solubility and penetration through the rectal mucosa must be obtained, requiring some compromise in properties of choice. It has often been observed that *in vivo* differences are often less pronounced than *in vitro* differences. Furthermore, penetration enhancing agents can often improve the delivery of relatively large water-soluble drugs.

Nonspecific adsorption

The surface properties of a solid may significantly affect the drug when it reaches the interface between the vehicle and the rectal fluid. The amount of wetting, as

demonstrated by contact angle, that occurs or changes in the interfacial tension as caused by interactions with surface-active agents in the vehicle or rectal fluid may have a profound effect on dissolution and consequent absorption of the drug. This can often increase the availability of the drug. On the other hand, adsorption or complex formation with surface-active agents may reduce the availability of the drug and its absorption.

Spreading of the administered formulation

For optimal drug absorption, it is important that the suppository or vehicle melts or dissolves rapidly and spreads over the rectum walls. Thus the rheological behavior of the vehicle can have a significant effect on the release of the drug and the ability of the drug to come into contact with the rectal mucosa. Several studies have suggested that the viscosity of the vehicle is very important for the release of the drug from the vehicle. Studies that compare the spreading behavior of suppository bases and their hydrophilic-lipophilic balance (HLB) values have been inconclusive. Although spreading directly determines the area from which release from the vehicle can occur and thus absorption, there is also the potential difficulty that concentration and thermodynamic activity of the drug may be reduced if it is allowed to spread too much and particularly too high up the rectum. This may result in absorption by the upper hemorrhoidal vein and into the portal blood supply with increased first-pass metabolism.

Yahagi et al. (3) have reported improvements in lidocaine bioavailability utilizing a unique double phase suppository that minimizes spreading of an administered suppository. The front or anchoring phase of the suppository contains Witepsol-H15, Carbopol, 934P, and wax. The terminal layer or drug releasing layer contains Witepsol-H15, Carbopol 934P, and lidocaine. Carbopol provides the bioadhesive properties and the wax confers physical strength to the suppository formulation. This formulation provided greatly prolonged plasma lidocaine levels with improved bioavailability. The authors suggest that a combination of improved rectal retention (decreased formulation migration due to bioadhesive nature) combined with a somewhat slower drug release rate maximizes avoidance of absorption into vascular pathways subject to first-pass hepatic metabolism. This approach may prove useful for drug candidates subject to high first pass effects.

Optimizing Drug Absorption

Enhancing agents

Over the past 20 years, a variety of agents have been identified which significantly increase the permeability of

the GI tract to drug absorption. The enhancing action of a variety of absorption-promoting adjuvants on rectal absorption has been extensively discussed (33). Included are acylcarnitines (19), acylcholines (19), salicylates (34), bile salts (35), phenothiazine derivatives (36), enamines (37), and fatty acids (38). Strong chelating agents and phenothiazines appear to enhance the rectal absorption of both low and high molecular weight compounds with a constant ratio of absorption via a paracellular route. Diethylmaleate enhances rectal absorption of low molecular weight compounds via a transcellular route. Various salicylates, diethyl ethylene malonate, and various fatty acids have been found to enhance both the paracellular and transcellular routes of absorption (33). In some respects, rectal drug administration is optimally suited for coadministration of drug entities with absorption-enhancing agents.

Work in the authors' laboratories has clearly shown that the presentation profile of drug and enhancing agent is critical to optimal activity (19). With agents like the acylcarnitines and acylcholines, the effective increase in permeability due to absorption enhancement is transient with nearly complete loss of activity approximately 30–60 min after dosing. In order to take advantage of the narrow time window of increased permeability, it is essential that the drug and enhancing agent be present at the mucosal barrier at the same time and in sufficient concentration to effect the permeability change. The low motility and limited fluid content of the rectal compartment is ideal for optimizing these requirements. When administered orally, enhancing agents are routinely less effective than when given rectally, presumably due to motility and dilution of the drug and enhancer. The necessary temporal and spatial dosing of a drug and enhancer can be achieved more readily via the rectal than the oral route. Design and performance determination of solid rectal suppositories must, however, address the release profiles of both agents which adds to the complexity of the formulation process. This can be achieved, as demonstrated in a previous study, with sodium cefoxitin and salicylate-type enhancing agents (20). In this study, a rectal suppository of the antibiotic with enhancing agent was shown to be essentially bioequivalent to an intramuscular injection of the antibiotic alone. The rectal absorption of proteins can also be enhanced by salicylates, as shown for insulin in Fig. 2. As an alternative to injectable administration, a rectal suppository offers definite advantages in terms of patient compliance and out-of-clinic administration.

pH control

As discussed earlier, the pH of the rectal fluid can have a marked effect on the absorption of drugs from the rectum.

Since the rectal fluid has a relatively low buffering capacity and the volume of the rectal fluid is small, it might be expected that the contents of the rectal dosage form largely control the pH of the rectum during administration. On this basis, one may be able to utilize the pH characteristics of the drug and incorporate suitable buffers and other excipients in the dosage form to control the pH. It has been reported (40) that a solution having a buffer capacity of 0.1 was sufficient to maintain a pH at about 5.9 during perfusion in humans. In this study, the pH was restored to normal at a rate of about one half a pH unit per minute, following removal of the perfusate. The body appears to try to maintain the pH at the absorbing surface relatively constant by secretion but often requires some time to be able to return to the normal pH after administration of a rectal dosage form having significant buffer capacity and differing pH.

Solubilizing agents

It would be expected that solubilizing agents may increase the rate of drug release from a suppository base by increasing the dissolution rate and perhaps by modifying the viscosity and interfacial tension of the vehicle with the rectal fluid. In addition to the effect that a solubilizing agent or a surfactant can have on the drug and the vehicle, the surfactant may also have an effect on the mucous coating of the rectal membrane. This may increase absorption by reducing the thickness of the layer through which the drug must traverse or it may act as a penetration enhancer by increasing the permeability of the membrane through damaging the rectal mucosa. Nishihata et al. (39) reported that sodium lauryl sulfate appears to interact with the lipoidal fraction of the rectal membrane with irreversible effects in the short term. It was further reported (41) that various metabolic inhibitors had little, if any, effect on the enhancement observed with the surfactant polyoxyethylene 23-lauryl ether. However, definitive studies have not been reported which clearly delineate the complexities that can occur from the simultaneous involvement of several factors that influence drug absorption from the rectum. It has been suggested that for an oleaginous base, solubilization, particularly with a decrease in vehicle viscosity, should improve rectal drug delivery.

Viscosity modifiers

The luminal pressure of the rectal mucosa can act as a shearing stress and influence the rheological behavior of substances showing either plastic or pseudoplastic behavior. It is possible that the viscosity at the shearing stress supplied by the rectum is more important than the yield value of the suppository. It appears that viscosity is very important for drug release from suppositories where

Fig. 2 (a) Concentrations of glucose (mg/100 ml) and insulin (μ IU/ml) in the plasma of dogs following an intramuscular injection of 10 IU of insulin. (b) Concentrations of glucose and insulin in the plasma of dogs after the administration of a 0.5 ml microenema containing 20 IU of insulin with 150 mg of sodium 5-methoxysalicylate in a 0.9% NaCl solution containing 4% gelatin. (c) Concentrations of glucose and insulin in the plasma of dogs following a 0.5 ml microenema containing 20 IU of insulin with 300 mg of sodium salicylate in a 0.9% NaCl solution containing 4% gelatin. (From Ref. 39.)

the melted material behaves like a Newtonian fluid. Generally, the lower the viscosity, the quicker and more complete the release of the drug from the vehicle and the higher the absorption of the drug.

FUTURE OF RECTAL DRUG DELIVERY

Market Potential

Even under the best of conditions and therapeutic needs, rectal dosage forms will remain only an alternative to oral administration. Due to problems associated with patient acceptance and compliance, the need to refrigerate many suppository bases, and the inconvenience of dosing, it is extremely unlikely that rectal drug administration will ever play a significant role in the pharmaceutical market. However, in specific fields of the therapeutic regimen, rectal dosage forms can have a significant impact and can address the needs of several patient populations that are poorly fulfilled by conventional oral formulations.

Examples Where Oral Administration Does Not Satisfy Therapeutic Needs

For certain groups of the patient population, oral dosing is either not desirable or impossible. Several antibiotics which are administered postoperatively via parenteral routes are not available as oral formulations because of the nature of the drug or its absorption limitations, or they are unacceptable due to swallowing difficulties in this patient subset. In these cases, rectal formulations that can contain a significantly higher drug content than oral formulations and which can be administered without difficulty to hospitalized patients, offer an attractive alternative and can be utilized to wean patients from parenteral to non-parenteral drug delivery. Rectal formulations of medications for pain control and sedation fit within this postoperative category.

Both children and the elderly experience swallowing problems with oral formulations. A limited market already exists in pediatric therapeutics which addresses this problem. Although development of rectal formulations for the elderly has not been addressed extensively, with the expanding number of patients in this age group, the need

for acceptable alternatives to oral dosing may increase efforts to develop rectal formulations.

As indicated previously, two general classes of drugs may be most amenable to formulation in rectal dosage forms. Drugs which require relatively high dosing, such as many of the antibiotics, are good candidates for rectal formulations which minimize the need for multiple oral dosings in order to reach the desired drug levels. Drugs that are substrates for proteolytic activity in the upper GI tract, particularly peptides and proteins, may find a useful application in rectal dosage forms if their absorption profile can be improved. Finally, in some very specific cases where extensive first-pass metabolism limits a drug's usefulness, rectal formulations may provide an attractive alternative.

SUMMARY

Rectal administration of therapeutic agents represents a narrow part of the total pharmaceutical approach to disease management but it holds promise for increasing applications. Although rectal administration will not become the first line of drug delivery, the increasing pressure to find exploitable delivery routes for peptides and proteins may well find some answers in rectal administration. From a drug stability perspective, the low level of proteolytic activity in the colon and rectum offers hope that active agents can be delivered to the cellular membrane in effective concentrations. Assuming that techniques can be developed to increase the permeability of the GI tissue to these agents, rectal administration may become a more widely employed route of delivery.

Drug Delivery—Pulsatile Systems

INTRODUCTION

Historically, extended release dosage forms were developed, which release the drug continuously over longer periods of time. These dosage forms offer many advantages, such as the nearly constant drug levels at the site of action and therefore minimization of peak-trough-fluctuations, reduced frequency of administration, and an improved patient compliance. In recent years, pulsatile release systems have gained increasing interest. Ideally, with a pulsatile system, the drug is released rapidly and completely after a defined lag time of no drug release (Fig. 1A). Alternative terms used to describe pulsatile release are delayed or sigmoidal release. Besides one-pulse systems, multipulse systems release the drug in subsequent pulses.^[1] The application of pulsatile release systems can be advantageous to adapt a drug therapy to chronopharmacological needs or to target a drug to a specific site in the gastrointestinal tract (GIT), e.g., to the colon.

Pulsatile drug delivery systems (DDS) can be classified in site-specific and time-controlled systems. Drug release from site-specific systems depends on the environment in the GIT, e.g., on pH, presence of enzymes, and the pressure in the GIT. In contrast, time-controlled DDS are independent of the biological environment. The drug release is controlled only by the system. Time-controlled pulsatile delivery has been achieved mainly with drug-containing cores, which are covered with release-controlling layers. The cores serve as reservoirs, which protect the core from the environment, e.g., water, acidic pH, and enzymes, until the drug is released after the lag phase. The coatings can erode/dissolve, rupture, or alter their permeability at the required time. Alternatively, capsular-shaped cores can be combined with release-controlling plugs. These strategies to release drugs in a pulsatile manner are reviewed in detail in this article.

CHRONOPHARMACOLOGY OF DRUG EFFECTS

The dependence of several diseases and body function on circadian rhythms is well known. A genetic control of a

“master clock” located in the nucleus suprachiasmaticus was recently proposed.^[2]

A number of hormones, such as renin, aldosterone, or cortisol, show distinct daily fluctuations.^[3] Circadian rhythms in the onset and extent of disease symptoms were observed, including diseases such as bronchial asthma, myocardial infarction, angina pectoris, rheumatic disease, ulcer disease, and hypertension.^[4]

The incidence of asthmatic attacks increased during the early morning hours with a maximum at 4 A.M.^[5] (Fig. 2). A treatment based on a theophylline controlled release dosage form resulting in a constant drug plasma level would not be optimal. Therefore a therapeutic scheme taking into account diurnal variation should be more effective. This could be realized by a pulsatile dosage form, taken at bedtime with a programmed drug release in the early morning hours.

Circadian effects were also observed for the pH and acid secretion in the stomach. Despite treatment of patients with a continuous infusion of famotidine, a H₂ antagonist, the pH in the stomach showed diurnal fluctuations between pH 7 and pH 2–3.^[6] Therefore a constant blood level, as obtained with a drug infusion and possibly achieved with conventional controlled drug delivery systems, does not always lead to a constant pharmacological effect. Similar effects were observed for the gastric pH in ranitidine-treated patients.^[7] Another example for the need of chronopharmacological adaptation is the treatment of pain in a study with patients suffering from post-operative pain. The analgesia requirements followed a diurnal rhythm with peaks at 9 A.M. and 8 P.M.^[8]

Chronopharmacology can affect the drug therapy in two ways, either in daily variations in pharmacodynamic effects or in pharmacokinetics.^[9] Many drugs were studied with respect to their pharmacokinetics and chronopharmacology, including analgesics, anticancer drugs, antibiotics, psychoactive drugs, local anesthetics, anti-asthmatics, anticonvulsants, and beta-blockers.^[10] Beta-receptor blocking agents reduced ischemic events mainly during the morning hours.^[11]

All body functions involved in absorption, distribution, and elimination of drugs can be dependent on circadian rhythms. For example, the gastric emptying time of solids

Fig. 1 Drug release profiles: (A) pulsatile, (B) and (C) conventional extended release.

is faster in the morning than in the afternoon.^[12] Blood perfusion of the gastrointestinal tract was also found to be higher during early morning hours, which could affect the absorption via passive diffusion.^[13,14] Especially for lipophilic drugs, the time of maximum plasma concentration, t_{\max} , may decrease and maximum plasma concentration, C_{\max} , may increase when applied in the morning hours.

These findings lead to the requirement of a time-programmed therapeutic scheme, whereby the drug is at the site of action at the right time in the required amount. This can be realized with pulsatile drug delivery systems.

SYSTEMS WITH ERODING OR SOLUBLE COATINGS

Most pulsatile delivery systems are reservoir devices coated with a barrier layer. The barrier dissolves or erodes

Fig. 2 Incidence of asthmatic attacks in about 1600 patients during a 24-hr cycle. (From Ref. [5].)

after a specified lag time, after which the drug is released rapidly from the reservoir core. In general, the lag time prior to drug release can be controlled by the thickness of the coating layer.

Various lag times have been achieved with press-coated tablets, where the press-coated barrier layer consisted of a mixture of a soluble polymer, hydroxypropylmethyl cellulose (HPMC), and different water-insoluble polymers, such as ethylcellulose, Eudragit[®] RS, or polylactic acid in different ratios.^[15] The release medium permeates through the coating and then results in disintegration of the tablet, whereby the lag time prior to disintegration decreases with increasing proportion of the water-soluble polymer.

The Chronotopic[®] system (Fig. 3) consisted of a core tablet containing the drug and a HPMC layer, optionally coated with an outer enteric coating.^[16–19] The lag time prior to drug release was controlled by the thickness and the viscosity grade of the HPMC layer. After erosion or dissolution of the rubbery HPMC layer, a distinct pulse was observed. To avoid retarding effects in the drug release phase, the thickness as well as the viscosity grade of the HPMC layer should be limited.^[20] The system probably works best for poorly water-soluble drugs. Highly water-soluble drugs could possibly diffuse through the swollen HPMC layer prior to complete erosion. In addition to core tablets, this principle was applied to hard and soft gelatin capsules.^[21] The coating was applied by spraying an aqueous solution of HPMC (Methocel[®] E50) onto the capsules up to a weight gain of 20%. The lag time of coated capsules was longer than that of tablets at the same coating level. This was explained by the lack of disintegration power of the capsules, when compared to the coated tablets. One problem of the coated tablets was the attrition of the swollen polymer from the edges during dissolution test; this would also lead to shortened erosion rates.

The following examples describe delivery systems, whereby an impermeable, insoluble layer protects several

Fig. 3 The Chronotopic[®] system. (From Ref. [18].)

sides of the system from the dissolution medium and the drug release therefore occurs only from one side of the system.

Lippold and Möckel proposed a prototype, which consisted of a three-layer HPMC tablet, containing, from the outside to the inside, an immediate release layer, an intermediate drug-free layer, and an inner drug-containing layer (second pulse dose of drug).^[22] A specially designed holder, a tight-fitting metal mould, was used to allow only one surface to come into contact with the release medium. The hydrophilic matrix eroded continuously, first releasing the drug from the immediate release layer, followed by a period of no drug release (the length of which was controlled by the thickness and therefore the erosion time of the intermediate drug-free HPMC layer) and then the second drug release pulse from the inner layer. The release profile showed a sharp increase in the beginning (first pulse; immediate dose from the top layer released), followed by a lag time, and again a drug release phase (second pulse). The lag time increased from 2.5 to 6.5 hr with increasing thickness of the HPMC layer from 1.44 to 2.87 mm. The HPMC swelled and formed a gel-like layer, thus reducing the release rate of the second pulse. This system was suggested as a prototype for a buccal tablet because of the limited transit time of a solid dosage form through the stomach and the small intestine. A buccal application supposedly would overcome this limitation.

For a final dosage form, a coating for the three sides of the system is still needed in order to overcome the need of the metal mould, which was used during the *in vitro* tests.

A release pattern with two pulses was obtained from a three-layer tablet consisting of two drug-containing layers, separated by a drug-free gellable polymeric barrier layer.^[23,24] The three-layer tablet (Fig. 4) was coated on three sides with an impermeable coating (labeled d), consisting of ethylcellulose. Upon contact with dissolution fluids, the initial dose incorporated into the top layer (a) was released rapidly from the uncoated tablet surface. The second pulse was obtained from the bottom layer (c) after the gelled barrier layer (b) was broken by expanding disintegrants present in the bottom layer. The superdisintegrants were cross-linked polyvinylpyrrolidone

Fig. 4 A three-layer pulsatile system. (From Ref. [25].)

(crospovidone, Polyplasdone[®] XL) and sodium starch glycolate (Primojel[®]). The lag time could be controlled by the choice of the gelling materials (HPMC types with different molecular weight). However, the drug dissolution period after the lag time was quite long due to the loss of swelling efficiency of the disintegrants present in layer (c), which slowly absorbed moisture during the slow gelation of the barrier.^[25] Two distinct plasma peaks obtained *in vivo* (1 hr and 4.5–5 hr after administration) corresponded to the *in vitro* results (immediate release and a second dose released after 40 min). The deviation between *in vitro* and *in vivo* lag time for the second dose was not explained. The main drawback of this dosage form was the complicated manufacturing procedure, including the coating process. The coating step had to avoid the coating of one side (release side) of the tablet, which was obtained by manual coating with a special designed tablet holder. The design of this dosage form has been improved by the application of a press-coating procedure (instead of spray-coating) using a high viscosity HPMC grade.^[26] The obtained lag times ranged from 2 to 3 hr for diclofenac, tested in deionized water, and from 2 to more than 10 hr for ibuprofen, tested in pH 7.5 medium. Although the composition of the system was the same, the ibuprofen-containing tablet showed longer lag times. The authors explained this observation with the use of different dissolution media.

Press-coated tablets were produced on modified rotary tablet machines using special tools with hollow punches, where first an inner tablet was formed and then the outer shell was compressed in the same die (“tablet-within-a-tablet”).^[27]

Another dosage form with an erosion-controlled lag time had a drug-containing core, which was incorporated into a compressed, hollow cylinder consisting of hydroxypropyl cellulose (HPC).^[28] The flat surfaces of the tablet were coated with an impermeable polymer, poly(ethylene vinyl acetate) (Fig. 5). The delivery system was prepared by hand: a hole was drilled into a tablet to obtain the hollow matrix, the inner drug core was placed into this hole, and the system was coated by hand on the two flat base surfaces. This preparation would be quite complicated for large-scale manufacturing, and the use of a nonapproved polymer and benzene as a coating solvent would limit the application of this system. Lag times between 6 and 11 hr were achieved with either a fast drug release after the lag time (using microcrystalline cellulose or lactose in the core) or sustained release (with HPC in the core). The lag time increased with increasing thickness of the matrix cylinder. Lactose-containing cores developed an internal osmotic pressure, leading to a fast separation of the coating from the core. Thus drug was delivered before complete erosion of the outer HPC matrix. On the other hand, microcrystalline cellulose-cores had no osmotic effect, coating separation did not

Fig. 5 Eroding system with hollow cylinder and coated surfaces. (From Ref. [28].)

occur, and the lag time was longer. The complete erosion of the matrix was necessary to release the drug.

The lipid barrier of the Time Clock[®] system, containing carnauba wax and beeswax, eroded or was emulsified into aqueous media because of incorporated surfactants (polyoxyethylene sorbitan monooleate).^[29] The lag time increased with increasing coating thickness and was independent of the environmental pH. In vivo assessment with gamma-scintigraphy of an enterically coated Time Clock[®] system was in good agreement with the in vitro predicted data with regard to the lag time.^[30] When the viscosity of the dissolution medium of the in vitro test was raised to 120 cps, the lag time was prolonged to the same value as obtained with in vivo data. The advantage of this system was its ease of manufacturing without the need of special equipment. However, controlled release delivery systems based on lipids may have a high in vivo variability (e.g., food effects).

SYSTEMS WITH CHANGED MEMBRANE PERMEABILITY

The permeability and water uptake of Eudragit[®] RS or RL [chemical name, poly(ethyl acrylate, methyl methacrylate,

trimethylammonioethyl methacrylate chloride)], can be influenced by the presence of different counterions in the release medium.^[31] It was found that theophylline was released faster from Eudragit[®] RS-coated pellets, when succinic, acetic, glutaric, tartaric, malic, or citric acid are present in the release medium.^[32] Increased permeability was explained by the higher hydration of the film, also expressed as the “free volume.”

Several delivery systems with sigmoidal or pulsatile release patterns were derived on this ion exchange. The sigmoidal release system (SRS) consisted of pellet cores, containing drug and succinic acid, coated with Eudragit[®] RS.^[33] The lag time was controlled by the rate of water influx through the coating. The water then dissolved succinic acid and the drug inside the core, and the acid solution increased the drug permeability of the hydrated polymer film by interacting with the quaternary ammonium groups.

In a similar system, theophylline and sodium acetate, acting as the permeability modifying salt, were layered on sugar pellets, followed by coating with Eudragit[®] RS30D.^[34] The lag time increased with increasing thickness of the outer membrane. The slope of the drug release phase was independent of the thickness but was influenced by the amount of the salt in the system.

The release profile of systems based on permeability changes appeared to depend strongly on the physicochemical properties of the drug and its interaction with the membrane. A pulsatile release profile may be obtained for some particular drug molecules in a specific formulation but cannot be generally applied to all drugs.

RUPTURABLE SYSTEMS

The other class of reservoir-type pulsatile systems is based on rupturable coatings in contrast to the swellable/erodible layers of the previous section. The drug is released from a core (tablet or capsule) after rupturing of a surrounding polymer layer, caused by a pressure build-up within the system. The pressure necessary to rupture the coating can be achieved with gas-producing effervescent excipients, an increased inner osmotic pressure or swelling agents, such as cellulose ethers, polysaccharides, or superdisintegrants.

Drug-containing tablets with an effervescent mixture of citric acid and sodium bicarbonate coated with ethylcellulose resulted in a pulsatile release after rupturing of the coating, which was caused by the carbon dioxide development after water penetration into the core.^[35] The rupturing strongly depended on the mechanical properties of the coating layer: highly flexible films, such as Eudragit[®] RS, with high elongation and low elastic moduli, ruptured after a certain lag time as a consequence of the effervescent reaction but left only small fissures

within the film. Therefore the drug release was prolonged and not immediate after the lag time. Using a mechanically weaker and nonflexible film, such as ethylcellulose, plasticized with 20% w/w DBS, the drug release was sigmoidal and reproducible (Fig. 6). The lag time before drug release increased with increasing coating level. Moreover, the disintegrant properties of microcrystalline cellulose, which was primarily used as a filler, supported the film rupturing.

Osmotic pressure was the mechanism of a rupturable dosage form, which was proposed by Baker in 1976.^[36] The core tablet, which contained a drug and a disintegrant, was coated with cellulose derivatives such as ethylcellulose or cellulose acetate. The core protection was defined as the time until the coating ruptured and the drug was released.

Another system was based on a swelling core tablet and a surrounding coating consisting of a combination of hydrophobic and hydrophilic polymers.^[37] The insoluble hydrophilic polymer, such as calcium pectinate or calcium alginate, was dispersed in the coating and served as a channel-former in order to control the water penetration. The core contained a swelling, but water-insoluble polymer, a hardness enhancer (microcrystalline cellulose), and a disintegrant to achieve a fast disintegration after the membrane burst.

Also, soft and hard gelatin capsules could be coated with a swelling layer followed by coating with a rupturable polymeric layer^[38] (Fig. 7). Superdisintegrants, such as Ac-Di-Sol[®] (croscarmellose sodium) or low-substituted hydroxypropyl cellulose (L-HPC), were used as swelling substances, which resulted in a film rupture followed by a rapid drug release. Ethylcellulose or cellulose acetate forms the outer rupturable polymeric membranes. The lag time was controlled by the composition of

Fig. 6 Pulsatile drug delivery system based on coated effervescent cores—influence of the coating level (7% and 15% w/w) and hardness (50 and 100 N) on the drug release/lag time (coating, EC/DBS; core, 30%, w/w, effervescent agents, microcrystalline cellulose). (From Ref. [35].)

Fig. 7 Capsule-based rupturing pulsatile delivery system. (From Ref. [38].)

the outer polymer layer. Water-soluble polymers such as HPMC increased the permeability and therefore reduced the lag time. The advantage of these capsule-based systems was that both solid and liquid drug formulations could be delivered.

The systems described above are single unit systems. The rupturing of the outer coating of the individual units of a multiple unit dosage form can be induced by the same principles as described for single unit systems.

Multiparticulate drug delivery systems (e.g., pellets) have various advantages, when compared to single unit dosage forms.^[39] These advantages include a reproducible and generally short gastric residence time, no risk of dose dumping, and the flexibility to blend pellets with different compositions or release patterns. However, the potential drug loading of a multiparticulate system is lower because of the proportionally higher need for excipients (e.g., sugar cores).

The time-controlled explosion system (TES) was a multiparticulate system, whereby the drug was layered on an inner core, followed by a swellable layer (e.g., hydroxypropyl cellulose) of optimal thickness (at least 180 μm) and an insoluble polymeric top layer (e.g., ethylcellulose).^[40–43] Upon water ingress, the swellable layer expanded resulting in film rupturing with subsequent rapid drug release. The release was described to be independent of the environmental pH and drug solubility. The lag time increased with increasing coating level and higher amounts of talc or lipophilic plasticizer in the coating, and the release rate increased with increasing concentration of the osmotically active agents. In vivo studies of the time-controlled explosion system, which had an in vitro lag time of 3 hr, showed first drug blood levels after 3 hr and maximal blood levels after 5 hr.^[44]

A combination of osmotic and swelling effects was used in the system developed by Amidon and Leesman.^[45] The permeability-controlled systems consisted of a core, containing an osmotically active substance, a swelling substance, and the drug. NaCl and sorbitol were used as osmotic substances and Na carboxymethyl cellulose as the swelling material. These cores were coated with an

insoluble, semipermeable polymer, such as cellulose acetate. The time T_P , when the insoluble film ruptured, was described by the following equation:

$$T_P = \frac{V_e^* + V_d}{A \cdot a \cdot L_P \cdot \Delta\pi}$$

where T_P represented the time until film rupture (lag time), V_e^* was the volume, to which the tablet has to be expanded for film break, V_d was the displaceable volume inside the core, A was the surface area of the film, a was a constant, L_P was the water permeability of the film, and $\Delta\pi$ was the osmotic pressure difference across the film. The constant a was

$$a = \frac{\Delta r^* / r_0}{e^*}$$

where Δr^* was the critical radius increase, r_0 was the initial radius of the unit, and e^* was the critical strain. This model was based on the following assumptions: the units (tablets, pellets) have a spherical shape, the thickness of the film and the osmotic pressure difference are constant, and the values of the critical stress and strain for film rupture do not change. In practice, the changing mechanical properties of the film, the changing permeability, and weak points (defects) of the film would have to be considered.

Chen has proposed a system with a core, containing an osmotically active substance (NaCl) and the drug, which was coated by an insoluble, permeable membrane.^[46] The coatings included different types of polyacrylate-poly-methacrylate-copolymers (Eudragit[®] NE30D, Eudragit[®] RS30D) and magnesium stearate, which reduced the water permeability of the membrane, thus allowing the use of thinner films for long lag times. Otherwise, thicker films had to be used, which were more difficult to rupture.

The lag time of a similar system was controlled by the addition of an enteric polymer to the surrounding insoluble membrane polymer (e.g., ethyl cellulose). The enteric polymer, poly(methacrylic acid-methylmethacrylate) copolymer (Eudragit[®] S) or hydroxypropyl methylcellulose phthalate (HPMCP), did not dissolve in the acidic pH of the stomach but dissolved in the small intestine, thus weakening the membrane and resulting in rupturing after a predetermined time. Expanding of the core upon water ingress was achieved by the presence of Explotab[®] (starch glycolate), a swelling substance. Again, the inclusion of water-insoluble agent (magnesium stearate) in the outer membrane resulted in thinner, less permeable films with better rupturing properties.^[47]

An osmotically active, drug-containing pellet core has been coated with cellulose acetate, a semipermeable polymer, which is permeable for water but impermeable for drugs.^[48,49] The lag time increased with increasing

coating level and higher amounts of talc or lipophilic plasticizer in the coating, and the release rate increased with increasing concentration of the osmotically active agents. The addition of osmotically active salts, such as sodium chloride, was necessary to achieve a pulsatile release. Otherwise, the release was extended after the lag time because of the lower degree of core swelling, which resulted in only small fissures and not in a complete rupturing of the coating.

Heng et al. investigated multilayered pellets, containing neutral core pellets, an inner drug layer, an intermediate HPMC layer (swelling layer) and an outer insoluble diffusion layer, consisting of Eudragit[®] RS. The addition of sodium chloride to the HPMC layer decreased the rate of swelling and thus delayed the bursting of the pellets.^[50] This phenomenon was first unexpected because of osmotic effects of the salt, which should promote water uptake. The longer time until rupturing was explained by the competition between sodium chloride and HPMC for the imbibed water.

A theoretical approach to calculate the burst time from an osmotically active spherical capsule, which depended on the initial radius, wall thickness, osmotic pressure of the contents, and the material of the capsule, has been presented.^[51] This approach assumed that the spherical core increases in size upon osmotic water influx, leading to an elongation of the membrane until a certain yield stress is reached to rupture it. The rate of volume increase was described by the following equation:

$$\frac{dV}{dt} = D \frac{A}{l} (\Pi_0 - p)$$

where dV/dt was the rate of volume increase, D the dialysis permeability through the wall, A the area of the sphere, l the wall thickness, Π_0 the osmotic pressure difference across the wall, and p the internal pressure of the sphere.

The dimensionless values, $N_1 = \frac{Y}{M}$ and $N_2 = \frac{\Pi_0 r_0}{2Ml_0}$ (whereby Y was the yield stress at which the sphere bursts, M was Young's modulus of elasticity, r_0 the initial radius, and l_0 the initial wall thickness), were derived from the volume of a sphere and Hook's law for elastic materials. N_1 determined the radius, at which the spheres burst, and is the ratio of the material properties, yield stress (Y), and Young's modulus, a value for the stiffness, (M). N_2 determined the initial expansion rate. It was concluded that the dimensionless burst time, t_b^* , increases with increasing N_2 . When $N_2 > 2N_1$, the burst time t_b^* is proportional to l_0 . But if $N_2 < 2N_1$, the bursting time becomes sensitive to the other values.

Increased permeability and decreased wall thickness, concomitant with appropriate mechanical membrane properties, would lead to a faster water influx and shorter lag times of such an expanding system.

CAPSULAR-SHAPED SYSTEMS

Several single unit pulsatile dosage forms with a capsular design have been developed. Most of them consist of an insoluble capsule body, which contains the drug, and a plug, which prevents drug release during the lag phase. Mechanisms of plug removal include dissolution, erosion, or induced pushing-out of the plug by swelling or osmotic pressure.

The Pulsincap[®] system consisted of a water-insoluble body (hard gelatin capsule coated with polyvinyl chloride), filled with the drug formulation.^[52,53] The capsule

half was closed at the open end with a swellable hydrogel plug. Upon contact with dissolution media or gastrointestinal fluids, the plug swelled and pushed itself out of the capsule after a lag time, followed by a rapid release of the capsule content (Fig. 8). The lag time prior to the drug release was controlled by the dimension and the position of the plug. In order to assure a rapid release of the drug content, effervescent agents or disintegrants could be included in the drug formulation, in particular, with water-insoluble drugs. Studies in animals and healthy volunteers proved the tolerability of the formulation (e.g., absence of gastrointestinal irritation).^[54] In order to overcome the

Fig. 8 The Pulsincap[®] system. (From Ref. [51].)

potential problem of variable gastric residence time of a single unit dosage form, the Pulsincap[®] system was coated with an enteric layer, which dissolved upon reaching the higher pH regions of the small intestine. This allowed a more precise control of the drug release after passage of the stomach, because the transit time in the intestinal tract is less variable.^[55,56] The major drawbacks of the Pulsincap[®] system, which led to the withdrawal of commercial activities with this system, were the complicated manufacturing process, reproducibility problems, and the use of a plug material, a cross-linked polyethylene glycol based polymer, which has not been approved in pharmaceutical products.

As an alternative to swellable, cross-linked plugs, erodible plugs have been investigated for Pulsincap-like systems (Fig. 9). The tablet-shaped plugs can be produced by compression of a water-soluble, swellable polymer, such as HPMC, PVA, or polyethylene oxide.^[57] After contact with gastrointestinal fluids, the polymer plugs swelled quickly, forming a gel, followed by a transition into a sol and a subsequent period of erosion. The swelling polymer could also be combined with soluble low-molecular weight excipients, e.g., lactose, to reduce the lag time.^[58] In general, the lag time was adjusted by the choice of the molecular weight of the erodible polymer and by the thickness of the plug.

Plug degradation could also be achieved by enzymes being directly incorporated into the plug.^[59] In an example, plugs containing pectin, a natural polysaccharide, were degraded by pectinolytic enzymes, whereby the lag time of the system was controlled by the ratio of pectin to enzymes (Fig. 10).

Besides compression, erodible plugs were formed by a congealing method with melts of saturated polygly-

Fig. 9 Capsular-shaped pulsatile drug delivery system, consisting of an impermeable capsule body and (A) a swellable, insoluble coated plug and (B) an erodible plug. (From Ref. [56].)

Fig. 10 Chlorpheniramine maleate (CPM) release as a function of the pectin/enzyme ratio within the plug. (From Ref. [58].)

colyted glycerides (Gelucire[®]) or glyceryl monooleate (Myverol[®]).^[57]

Another approach was based on the use of an inner osmotic pressure to push out the plug from the insoluble capsule thus allowing drug release after the lag time. The Port[®] system was composed of a gelatin capsule coated with a semipermeable membrane (e.g., cellulose acetate), which was filled with an osmotic charge and closed with an insoluble plug (e.g., lipids such as Gelucire[®]).^[60] In contact with aqueous media, water diffused across the semipermeable membrane, resulting in a higher inner pressure and ejection of the plug after a certain lag time, which was mainly controlled by the coating thickness of the semipermeable membrane. The system was already tested in a human study, showing good agreement between lag times measured in vivo and in vitro.^[61] An additional immediate or sustained release dose could be placed between the soluble gelatin cap and the insoluble plug.

In the Chronset[®] system (Fig. 11), the driving force for the drug release was an osmotically active layer in the

Fig. 11 The Chronset[®] system. (From Ref. [61].)

semipermeable vessel, which pushed the cap out off the impermeable vessel after a predetermined time interval.^[62] The complete release of the drug, often problematic in capsular-shaped dosage forms, was ensured by an expanding layer at the bottom of the capsule body.

Even more sophisticated were insoluble high-frequency (HF) capsules, which released the drug in a pulsed fashion after a high-frequency signal was applied externally to the human body.^[63,64] These HF capsules were used to evaluate the absorption of drugs from distinct regions within the digestive tract. A similar capsule activated by an oscillating magnetic field has been published recently, which ejected an active compound or a radioactive marker to localize the position of the dosage form in the gastrointestinal tract.^[65]

In general, the large-scale manufacturing of the abovementioned capsular-shaped pulsatile drug delivery systems appears to be complicated. Special equipment and several manufacturing steps are necessary to combine all components.

CONCLUSION

The use of pulsatile drug delivery system should be taken into consideration for drugs with a chronopharmacological behavior, a high first-pass effect, the requirement of night time dosing or site-specific absorption in the GI-tract. In recent years, a wide variety of interesting single and multiple unit systems have been developed for oral application. However, many systems are only of academic use because of their complex manufacturing process or non-approved excipients. Most systems perform quite well in vitro, but their performance in vivo has often not been tested. One major challenge will be to obtain a better understanding of the influence of the biological environment on the release performance of pulsatile delivery system in order to develop simple systems based on approved excipients with a good in vitro/in vivo correlation.

DRUG SAFETY EVALUATION

Farrel L. Fort

TAP Pharmaceutical Products, Inc., Lake Forest, Illinois, U.S.A.

INTRODUCTION

Definition and Goals of Drug Safety Evaluation

Drug safety evaluation is the determination of the safety of drugs for use as therapeutic agents in humans or animals through the conduct of laboratory studies in animals and in vitro systems.

Drug safety evaluation studies are essential to

1. Differentiate between new drug entities that are unacceptably toxic and those that are not
2. Characterize the potential toxic effects of new drugs
3. Determine animal dosage levels that do not cause unwanted side effects and to estimate safe dosages to be used in clinical studies
4. Demonstrate the safety of pharmaceutical compounds or new drug formulations for marketing purposes
5. Support the marketing approval for new drugs by regulatory agencies.

Use of Drug Safety Evaluation Data

Drug safety data are used by scientists and management in the pharmaceutical industry to aid in making decisions about new drugs that can be chosen for further development. Drug safety data are necessary for approval of the Notice of Claimed Investigational Exemption for a New Drug (IND), which is required before clinical trials can begin. Clinicians conducting clinical trials refer to drug safety studies in animals for information on the side effects to be expected from the new drug and for guidance in selecting safe dosages to be used in the clinical trials. Extensive toxicology studies in animals are required for the New Drug Application (NDA) for marketing approval. Even after the marketing launch of the new drug, toxicology studies may be conducted to investigate new side effects reported after widespread clinical use. If new derivatives or new formulations of a marketed drug are discovered, toxicology studies may be conducted to determine whether the new derivative or formulation offers improved safety over the original product.

HISTORICAL PERSPECTIVE

Origins of Drug Safety Evaluation

Drug safety evaluation, as we know it today, is a relatively recent development. It probably began in the late 1930s in the United States as a result of several catastrophic events that illustrated to the public and to the Congress the need for safety testing on pharmaceutical products. These events stimulated legislation leading to regulations requiring animal safety tests before marketing of a new drug would be allowed.

Significant Events Stimulating Development of Drug Safety Evaluation

There have been several famous examples of marketed pharmaceutical products that poisoned hundreds or thousands of people (1). These examples focused the attention of the public, Congress, and the medical community on the need for safety testing of new pharmaceuticals before marketing.

During prohibition, alcoholic extracts of jamaica ginger became popular as an illicit beverage due to their 60 to 80% alcohol content. These extracts usually contained other ingredients, often including castor oil. One manufacturer in Brooklyn, New York, tried to avoid the rising price of castor oil by using triorthocresyl phosphate (TOCP) instead. TOCP is now well known to cause a delayed axonal neuropathy that results in paralysis or impaired use of the legs (known as "jamaica ginger paralysis," "ginger jake paralysis," or "jake leg paralysis"). Approximately 50,000 Americans were affected from 1930 to 1931.

In 1937, an oral formulation of sulfanilamide (sulfanilamide elixir), containing about 72% diethylene glycol, was marketed. Until that time, a suitable vehicle for an oral formulation of sulfanilamide was not available. The manufacturer chose diethylene glycol because the drug exhibited good solubility in that vehicle. Diethylene glycol is now known to cause kidney and liver damage when ingested in relatively large amounts, as occurred with sulfanilamide elixir.

About 350 people were poisoned by sulfanilamide elixir, and 105 died.

During the 1930s, dinitrophenol was touted as a weight-reduction drug. Dinitrophenol acts to uncouple oxidative phosphorylation from electron transport in the mitochondria, thereby stimulating the uncontrolled consumption of metabolic energy. This results in consumption of metabolic energy reserves, for example, fat. It also results in an elevation of body temperature. At least one person died from severe elevation of body temperature after taking an overdose of dinitrophenol. Dinitrophenol also causes cataracts; several hundred people developed cataracts as a result of taking dinitrophenol for weight reduction.

Thalidomide is the most publicized example of a disaster resulting from inadequate testing of a pharmaceutical prior to marketing. Thalidomide was never marketed in the United States but was very popular in other parts of the world, where it was taken as a sleeping aid and for colds, coughs, flu, nervousness, headaches, and asthma. It was used during pregnancy to control nausea. It was eventually reported that thalidomide causes a polyneuritis resulting in sensory and motor disturbances of the hand and thumb. However, it is best known for the induction of birth defects (e.g., phocomelia and amelia). During the late 1950s and early 1960s, over 10,000 babies were born deformed as a result of their mother's use of thalidomide during pregnancy.

Regulatory Events Influencing Development of Drug Safety Evaluation

In the United States, the regulatory environment allowing the development of drug safety evaluation as a distinct discipline began with the Food and Drug Act of 1906. This act provided governmental control over food contaminants, but provided no authority to ensure the safety of new drugs.

About the time of the sulfanilamide elixir episode, a senate bill, which was to become the new Food and Drug Act, was tied up in the House of Representatives. The publicity over the sulfanilamide elixir episode spurred Congress to pass the bill, which was signed into law in June 1938. This act created the Food and Drug Administration (FDA) and required that manufacturers of new drugs prove the product's safety to the FDA prior to marketing.

The thalidomide tragedy and the publicity it generated led to the passage in 1962 of the Kefauver–Harris Drug Amendments establishing the Investigation of New Drugs–New Drug Application (IND/NDA) system in the

United States. These amendments require that before clinical studies are initiated with a new drug, the FDA has to be informed of the intent to conduct clinical studies, the nature of the clinical studies, the qualifications of the clinical investigators, and the preclinical safety studies in animals demonstrating the safety of the new drug. This information is supplied to the FDA in the form of an IND application. The 1962 amendments also require proof of efficacy before a new drug is approved for marketing. This proof is obtained by conducting clinical trials and is submitted to the FDA as part of the NDA for marketing approval (1, 2).

Influence of the International Marketplace on Drug Safety Evaluation

The international pharmaceutical market has a tremendous financial impact on all the major pharmaceutical houses. Therefore, drug safety animal studies must be conducted to satisfy the requirements of regulatory agencies around the world. In practical terms, this means satisfying the requirements of the United States, Japan, the European Economic Community (EEC), and Canada because all the other countries in the world have less stringent requirements. In certain respects, the requirements of Japan and EEC are more stringent than those of the United States. Recently, the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) has developed guidances recommending international standards for nonclinical safety studies. These ICH guidelines serve to reduce differences among regional requirements and to reduce duplication of efforts needed to register a compound internationally. However, most countries not listed above approve new drugs for marketing if those drugs have previously been approved in the United States.

The development of regulations governing drug safety studies around the world has generally followed the development of regulations in the U.S. Such regulations were promulgated in the EEC in 1980, in Canada in 1981, and in Japan in 1984.

GENERAL PRINCIPLES

There are a few general principles followed in conducting drug safety animal studies in the development of new drugs. These principles and the reasoning behind them are sometimes misunderstood by those not involved in drug

safety evaluation, leading to unwarranted criticism of toxicology studies.

First, animal toxicology studies almost always use dosage levels higher than the intended clinical dosage. One of the goals of drug safety toxicology studies is to characterize the toxic side effects of a new drug. To characterize the toxicity of a new drug, high-enough dosages must be used to allow full expression of the toxic effects of the drug. The first goal stated in the introduction was to differentiate between drugs that are acceptably safe and those that are unacceptably toxic. One criterion by which this differentiation is made is the safety margin between the expected clinical dosage, or the pharmacologically active dosage, and the dosage that causes toxicity in animals. To determine this safety margin, dosages higher than the clinical dosage must be used. In addition, dosages in laboratory animals required to elicit pharmacological and toxicological responses are usually higher than those in humans, another reason why high dosages are used in animal toxicology studies.

Margin of safety is not the only criterion used to determine if a drug is safe enough to use in humans. The type of toxicity caused by the drug and the intended clinical indication are also considered. For example, a drug that might cause cancer would not be used for symptomatic relief of a head cold. However, such a drug might be used for the treatment of cancer as the disease to be treated is itself life-threatening. Many anticancer agents fall into this category. In other words, the benefit-to-risk ratio would be too low for the head cold but high enough for the treatment of cancer. This is an extreme comparison. Another example would be the teratogenic anticonvulsants in use today. These drugs can cause malformations in fetuses. Having a seizure during pregnancy also carries serious risk to the fetus and to the mother, however. The benefits of using an anticonvulsant during pregnancy are often considered to outweigh the risk of having a malformed child.

Reversibility of toxic effects is an important consideration in evaluating the safety of a drug. Cancer and fetal malformation are irreversible changes. If, instead of cancer a drug caused reversible enlargement of the liver, such a drug might be acceptable for less life-threatening diseases. In the case of the anticonvulsant used during pregnancy, a reversible retardation of neonatal growth would obviously be a more acceptable side effect than a malformation.

During the development of new drugs, reversibility of toxic effects is often studied to provide information for use in making benefit-to-risk decisions. The information is also helpful to the clinicians conducting clinical trials or using the drug if it eventually reaches the market. For the

clinician it is helpful to know that if a particular side effect appears in study subjects or patients, it will disappear upon cessation of treatment. The margin of safety derived from animal toxicity studies is not always infallible. During the clinical development program, it is often necessary to increase the dosage beyond that used in initial clinical studies. In this situation, where the margin of safety is decreased because the dosage has been increased, side effects are more likely to be encountered. If those side effects have been shown to be reversible in animal studies, the clinical investigators may feel more comfortable about raising the clinical dosage in order to achieve the desired pharmacological effect.

The conduct of animal toxicity studies proceeds concurrently with and in advance of clinical studies. A certain amount of animal toxicity data is required for the IND. This often includes acute toxicity in two rodent species, mutagenicity screening studies, and one-month toxicity studies in a rodent and nonrodent species. After the clinical studies have begun, further animal studies are conducted, usually until the time for the NDA. These would include further mutagenicity studies, reproductive toxicity studies, and long-term toxicity studies, possibly including carcinogenicity studies.

The duration of treatment in animal studies is always at least as long as the duration of treatment in clinical studies and, at the later stages of development, longer than in the intended therapeutic indication. This provides another element of safety. With long-term treatment, toxicity usually occurs at lower dosages than with short-term treatment. Some drugs may be found to accumulate in the body or in certain organs and thereby give rise to toxic changes at lower dosages than with short-term treatment. Occasionally with long-term treatment, different side effects may manifest themselves. If long-term toxicity studies are conducted in advance of long-term clinical trials, any changes in safety margin or toxicity profile will be known before the conduct of those clinical trials. The duration of treatment required by regulatory agencies for marketing approval is usually longer than the intended clinical regimen.

Another principle that is generally followed in drug safety evaluation is the use of two or more species to study the toxicology of a new drug. It is usually not possible to know which species will be the most accurate predictor of the toxicological response in humans. However, if a particular side effect is found in two or more species, we can predict that it will also occur in humans at high-enough dosages. In the case where a side effect is found at a lower dosage in one species than in another, the more sensitive species is generally used to estimate the safe dosage level for humans.

TYPES OF DRUG SAFETY EVALUATION STUDIES

Acute Toxicity

Acute toxicity studies are often misunderstood and criticized for the use of large numbers of animals to generate relatively valueless data, such as LD50 (a dosage that kills 50% of the test animals). It is worth pointing out that there are legitimate uses for such data. For example, in the early stages of new drug discovery, when no toxicity data of any kind are available, it is often very helpful to determine an LD50 for comparison with the ED50 (a dose that produces a pharmacological effect in 50% of the test subjects). This comparison is often used to calculate a therapeutic index (LD50/ED50): the higher the therapeutic index, the greater the implied margin of safety between the pharmacologically active and toxic dosages. These numbers can be generated quickly and inexpensively, helping to provide an early indication of the acceptability of a new drug for further development. Another way in which LD50 data are useful is in the quality testing of new batches of a drug. In mice, LD50 data are often routinely obtained for each new batch of bulk drug for comparison with the LD50 obtained on the original batch(es) of the same drug. This quick and inexpensive test gives a final assurance that the drug is not substantially different from the original drug, or has not been contaminated prior to preparation of the final formulation. To date, there are no good substitutes for these *in vivo* tests. Although they do consume large numbers of animals, the tests are quick, inexpensive, and reliable.

In addition to the applications of acute toxicity studies mentioned previously, such studies are necessary as the initial toxicity studies conducted in the development of a new drug. The information provided is used to select dosages for subacute and subchronic toxicity studies in which animals are treated daily for various periods of time. Studying the acute toxicity of drug combinations is a convenient method for detecting potential drug interactions that may occur clinically. If such interactions are detected, they may be studied further in subacute and subchronic toxicity studies. In these studies, a single dose of test compound is given to animals, which are then observed for a period of 1 or 2 weeks afterward for the development of toxic signs. Surviving animals are usually necropsied at the end of the observation period to determine if grossly observable organ changes have occurred. When organ changes are observed, these are usually examined microscopically to determine the nature of the change. If an LD50 is determined, it is usually calculated using probit analysis (3). Less often, the

up-and-down (4) or moving averages (5) methods, which require fewer animals, will be used. An LD50 value is not necessary for the safety evaluation of a drug or for choosing dosages for subacute toxicity studies. For these purposes, it is only necessary to determine the lowest lethal dosage of the compound and to characterize the toxic manifestations of an acute overdose. This information is useful to clinicians using the drug and to poison-control centers where information regarding the effects of acute overdose must be made available. To select dosages for repeated-dose, subacute toxicity studies, information about the lowest toxic dose is needed.

Often, an LD50 cannot be determined if the compound has low toxicity. Sometimes lethality or toxicity cannot be elicited. In these cases a "limit" dose concept is used. A limit dose, for example, 5 g/kg for rodents or 2 g/kg for dogs, is administered. If no deaths or signs of toxicity occur, the lethal or toxic dose is simply stated to be greater than the respective limit dose. Sometimes the limit dose may be determined by the volume that can be administered in a single bolus. In rodents, for example, 50 mL/kg is the maximum that can be given as a bolus orally or intravenously (IV). For IV acute toxicity, much higher dose volumes can be given if the drug solution is administered as a slow infusion.

The animals used in acute toxicity studies are usually mice, rats, and dogs. The batch tests mentioned above are usually conducted in either male or female mice. Females are generally more sensitive than are males, but either sex is appropriate. Because the objective is simply to compare the toxicity of a new batch of a given drug to that of previous batches, the absolute toxicity is less important than the toxicity relative to previous batches of the same drug. For the safety evaluation of a new drug, acute toxicity studies are usually conducted in both sexes of mice and rats by several routes of administration, including the intended clinical route(s). This is to generate initial information regarding differences in degree or type of toxicity resulting from different routes of administration [e.g., oral vs. IV vs. subcutaneous (SC) vs. intraperitoneal (IP)]. An initial indication of the degree of absorption can be obtained by comparing IV and oral toxicity. Sex differences in acute toxicity can alert the toxicologist to anticipate such differences in subacute/ subchronic studies. If sex differences are marked, this may be taken into consideration in deciding whether to pursue development of the compound. Because subacute and subchronic studies are usually conducted in rats and dogs, it is usually necessary to generate acute toxicity data in these species to aid in dosage selection for those studies.

There is increasing awareness in the industry regarding the need to reduce the numbers of animals used in acute

toxicity studies. This is because of social concerns about the unnecessary use of animals in laboratory studies and because of the financial impact of purchasing and housing large numbers of animals. The use of limit tests as outlined above and of alternative methods for calculating the LD50 offers practical means for reducing the numbers of animals used for acute toxicity studies.

Ocular and Dermal Irritation

If a drug is intended for use by ocular or dermal administration, one of the first requirements is to determine whether it could cause irritation upon contact with those tissues. Drugs or drug formulations that may inadvertently come into contact with the eye should also be tested for ocular irritation. For instance, a topical antibiotic that might be applied to the face could accidentally get into the eyes. Inhalation anesthetics also have the potential for ocular exposure.^a

Muscle and Vein Irritation

Muscle and vein irritation studies are conducted if a drug formulation is to be administered by these routes. These studies may be conducted as a guide during the development of formulations for these routes. They should be conducted prior to any subacute studies so that experimental animals are not subjected to avoidable pain and suffering.^b

Pain on Injection

It seems obvious that drug formulations to be given by injection should be tested for the amount of pain produced upon injection before being tested in humans. In practice, however, this kind of testing is rarely done unless a formulation is first tested in humans and found to be painful upon injection. The muscle and vein irritation studies mentioned previously sometimes give indications of pain if the animals show signs of discomfort during the injection. However, this is usually not a reliable indicator of the painfulness of the formulation. Muscle and vein irritation studies give information on the potential for drug formulations to cause tissue injury but not for pain on injection.

Models that do assess pain on injection are the rat paw lick and mouse scratch models. In the paw lick

model, the drug formulation is injected into the pad of the hindfoot, and the number of times the rat licks the paw is counted (6). The mouse scratch test is similar except that the formulation is injected subcutaneously on the back, and the number of times the mouse scratches the injection site is counted.

Results from the rat paw lick model seem to correlate well with clinical painfulness experience and the muscle irritation test with certain antibiotic formulations (6, 7). However, because rat paw lick results from a wide variety of drug formulations have not been published, these correlations may hold only for a certain subset of painful formulations. A formulation could cause pain but yet not cause muscle damage upon intramuscular injection. Additionally, some formulations are painful upon intravenous injection.

Subacute, Subchronic, and Chronic Toxicity

These studies are designed to characterize the toxic effects of drugs upon repeated daily administration for periods of time ranging from 2 weeks to 1 year and to determine no-toxic-effect dosage levels for short to long-term repeated dosing.

The studies are usually conducted in rats and dogs, unless one of these species is found to be inappropriate. This may be because of a sensitivity or insensitivity to the pharmacological effects of the drug which is not expected to be characteristic of the response in humans. The rat or dog may metabolize the drug substantially differently from humans. These animals may absorb the drug poorly relative to other species, or the pharmacokinetics may be substantially different. Such differences in pharmacological responsiveness, pharmacokinetics, or metabolism are almost never known when the initial toxicology studies are conducted. An exception would be the case of certain monoclonal antibody products with binding sites specific to primate tissues. In this case, primates would be selected as the only species in which to conduct safety evaluation studies. Genetically engineered human protein products where the antigenicity to primates is expected to be less than that to other species less closely related to humans, or where the pharmacological responsiveness in primates is similar to that expected in humans, might also be tested only in nonhuman primates. In most cases, the toxicology program is conducted in rats and dogs until one of these species is found to be inappropriate. The information that might lead to this conclusion would not be available until the Phase I clinical trials are conducted in healthy volunteers.

A certain amount of toxicology data is necessary, usually including 1-month studies in rodents and

^a For typical ocular and dermal irritation protocols, see *Animals in Drug Development*, page 000; 00000.

^b Typical protocols for these studies are described in the article, *Animals in Drug Development*, in this encyclopedia.

nonrodents, prior to the initiation of Phase I clinical trials. The studies are usually conducted in a sequential fashion, using the results from the short-term studies to design subsequent studies of longer duration. Thus, acute toxicity results are used to design 2-week studies, the results of which are used to design 1-month studies, which lead to 3-month studies, and then to studies of 6 month or 1 year. A typical study design would include a period of 2 weeks or more for quarantine and acclimation of the animals to the laboratory environment. During this time, measurements can be made (e.g., body weight, food and water consumption, urine output, serum chemistries, hematology, urinalysis, electrocardiograms (ECG), and general physical and ophthalmological examinations) to determine that the animals are healthy before beginning the treatment phase of the study. Excess animals are ordered and allowed to acclimate so that after unsuitable animals are rejected, a sufficient number of healthy animals remain to begin the study.

During the quarantine period, it is customary to have the animals examined by a veterinarian for signs of disease. In some cases, particularly in preparation for a long-term study where the financial risk is great, some of the animals from the shipment may be sacrificed, blood collected for serology to determine if viral antibodies are present, and the tissues examined for evidence of infectious processes.

During the conduct of the study, all the animals are carefully monitored for changes in physical appearance, behavior, body weight, and food consumption. These variables are often the most sensitive indicators of toxicity. During the study, the other variables mentioned above are periodically measured. The variables to be measured, the intervals between measurements, and the number of such measurements during the study depend on the drug under development, the length of the study, and on the species being used. For example, when dogs are used, blood samples for serum chemistry, hematology, or drug concentration determinations can be taken more frequently because of the larger blood volume relative to rodents and the ease of obtaining blood samples. However, if interim blood samples are required in rodents, extra animals are commonly included in each group to be used for this purpose. Because of the small blood volume in a rodent and the trauma inflicted when blood is collected, there is the possibility that the process of repeated blood collection could alter the response of the test animal to the toxic insult from the drug. This possibility will vary with the frequency of blood collections, the method of blood collection (e.g., tail bleeding, retro-orbital sinus bleeding, or cardiac puncture), and the nature of the drug under study. Many investigators prefer to avoid the possibility of

such confounding effects by assigning extra animals to provide blood samples. In a 1-month study, blood samples might be taken only during acclimation and at the end of the dosing period. However, if the time course of certain expected changes is of interest, then additional blood and/or urine samples may be taken after 2 weeks of treatment. In a 3-month study, samples might be taken at the end of every month or once every 6 weeks. In a 6-month study, samples might be taken every 3 months; in a 1-year study, once every 6 months. If a recovery period is included in the study design, then blood and/or urine samples would be taken at the end of the recovery period. If the recovery period is relatively long in duration, or if the time course of recovery of some function is important, samples may be taken at intervals during the recovery period. A recovery period is a period of time in which some of the animals in a study are held after the cessation of treatment to study the reversibility of any toxic changes that manifested during the treatment period. The length of recovery depends upon the nature of the toxic change under study, the duration of the treatment phase, and, to some extent, the species. For example, if the side effect caused by the drug results from an exaggerated pharmacological effect, for example, central nervous system (CNS) stimulation, cardiac arrhythmia, or hypertension, which might reverse fairly rapidly after the cessation of treatment, then a short recovery period would be appropriate. On the other hand, a change that might take longer to reverse, for example, testicular atrophy or hepatomegaly, would require a longer recovery period. In the absence of such qualifying circumstances (i.e., when the nature of the toxic changes to be expected is not known), typical recovery periods would be 2 weeks after 1 month of treatment, 1 month after 3 months or 6 months of treatment, and 3 months after 1 year of treatment.

Electrocardiograms are commonly recorded in dog studies but only rarely in rodents, although there is no good reason not to record ECGs in rodents. With the dorsal-axial-inferior (DAI) lead system (8), it is actually easier and faster to record ECGs in rats than in dogs. Furthermore, the rat heart is known to respond to pharmacological agents (except the cardiac glycosides) affecting the ECG of other species (8). Because of the more rapid heart rate of rat, the ECG is slightly more difficult to evaluate. However, the main reasons why ECGs are not recorded more commonly in rats in toxicology studies are custom and historical precedent.

It is also fairly easy to perform specialized measurements such as electroretinography in dogs without the anesthesia or surgical preparation required in other species (9, 10). Electroretinography has assumed a status of increased importance in safety evaluation because many

drugs affect retinal function. Examples are the quinolone antibacterials and Viagra (11).

At the end of the study, all the animals are killed under anesthesia, the internal organs are examined for visible changes indicative of pathological responses, the organs are weighed, and samples of all tissues are taken for histological examination. In some studies, particularly long-term studies, animals from each group may be killed at intervals during the study to collect tissues for histological examination. For example, in a 6-month study, some animals may be killed after 3 months of treatment; in a 1-year study, some animals may be killed after 6 months of treatment. Animals would also be killed at the end of any recovery period, or at intervals during the recovery period, for assessment of drug-related tissue changes. In studies with large animals (e.g., dogs or monkeys), protocols are sometimes written so that all the tissues from all the animals are examined histologically. However, in rodent toxicity studies, because of the large number of animals used, protocols are commonly written so that tissues from animals in the control and highest dosage groups killed at the end of the treatment period are examined first. If any changes are found that appear to be drug related, tissues from animals in the next lower dosage group are examined, and so on. Tissues from recovery group animals are usually examined only in groups where drug-related changes are found at the end of treatment.

The determination of the no-toxic-effect dosage level in a toxicity study is not always easy; often the only findings at a particular dosage level are those resulting from the pharmacological action of the drug, for example, hypotension and the resultant behavioral signs with a peripheral vasodilator or sedation with a tranquilizer. Are these changes to be considered due to toxicity? Certainly, they would be unwanted side effects of the drug, but on the other hand, they would not be unexpected based on the pharmacology of the drug. Other examples would be hepatocellular hypertrophy with a drug that also causes induction of liver microsomal enzymes, or renal enlargement at high dosages. These changes might be considered adaptive physiological changes. Should they be considered to be due to toxicity? Some investigators look for a slightly different end point in determining the results of a study—the no-observed-effect dosage level. In their view, all the examples just cited would be lumped along with other findings more clearly labeled toxicity into the category of drug-induced observed effects. They look for a dosage level below which no drug-induced effects are observed.

Dosage selection for subacute, subchronic, and chronic studies is always a sensitive matter, requiring experience and judgment. Three dosage levels plus one or more

vehicle or untreated control groups are usually used. The highest dosage is selected to elicit some degree of toxicity. It should not be so toxic that animals die or are debilitated before the end of the study. The purpose is to characterize the toxicity of the drug on repeated administration. If the dosage is too high, animals may be lost before the end of the treatment period. This reduces the number of animals available for terminal serum chemistry, hematology, histology, and so on, so that the toxicity cannot be characterized adequately. On the other hand, if the dosage is not high enough to cause toxicity, the study may be rejected as inadequate by regulatory agencies. The low dosage is usually selected to provide some small multiple of the expected clinical dosage or systemic plasma exposure level. In cases where the drug is fairly toxic, the low dosage may be selected to match the clinical dosage or plasma exposure level. However, it is usually considered necessary to demonstrate a no-toxic-effect dosage of at least 10 or 6 times the clinical dosage in the case of rats or dogs, respectively. Therefore, the low dosage is usually at least this multiple of the clinical dosage. The mid-dosage is selected to be at equal log intervals between the high and low dosages. This is because the response of biological systems to the vast majority of stimuli are logarithmic. Therefore, to best demonstrate a linear dose-response relationship, the stimulus should be administered on a logarithmic scale. In selecting the dosages for a study, it must be remembered that if the high dosage is toxic as expected, the mid-dosage is likely to be the no-toxic-effect dosage. Therefore, the relationship of the mid-dosage to the clinical dosage should also be considered when selecting the dosage scheme for a study. Often, it is desirable to compare the toxicity in long-term studies with the same dosages in short-term studies. If this is the case, some of the dosage levels in long-term studies may be the same as those in short-term studies. Although three dosage levels are usually considered the minimum, sometimes more dosage levels are used to meet all the considerations discussed above.

The number of animals per group depends on the length of the study, the species, whether a recovery period will be included, and whether extra animals will be included for blood sampling or other special procedures. Generally, for rodent studies to be submitted to a regulatory agency, 10 per sex is the minimum for studies up to 3 months, and 20 per sex is the minimum for longer studies up to 1 year. For dogs, at least 4 per sex is usually required in studies submitted for registration. More animals are preferred for long-term studies because the longer the study duration, the greater the chance of losing animals due to accidents or disease. The study design should compensate for the greater statistical chance of losing animals so that an

adequate number of animals are available at the end of the study for evaluation.

The route of administration is an important consideration in the design of a study. Generally, the route of administration in drug safety evaluation studies is the same route intended clinically. The most common route is oral. Drugs can be administered easily by gavage in rats, dogs, and monkeys and by capsule in dogs. Methods are available for administering capsules to monkeys and rats. In these cases, the capsule is usually affixed to the end of a special gavage needle for rats or gavage tube for monkeys. The tube is inserted into the stomach and the capsule expelled from the end of the tube. In long term (i.e., 1 year) rodent studies, it is common to administer drug mixed in the diet. This assumes that the drug is stable and bioavailable when mixed in the diet and that the drug can be mixed in a homogeneous manner in the diet. All these requirements must be demonstrated before committing to a dietary administration study. When administering drugs via the diet, it is necessary to adjust the drug concentrations in the diet to compensate for variations in food consumption by the animals and for changes in body weight. During the early stages, for example, the first 3 months, of the study when the animals grow most rapidly and when drug effects on food consumption and body weight gain are likely to be most pronounced, this should be done on a weekly basis. Later in the study, say, after 3 months, when the growth curve of rodents approaches a shallow slope, this can be done once per month. This is done by adjusting the concentration of drug in diet based on the food consumption and body weight gain from the previous period. The concentration for each sex group is adjusted separately. If an intravenous study is needed, this could limit the feasible duration of the study and/or the number of animals or groups that can be accommodated. If the drug formulation does not cause vein irritation, it is feasible to conduct 3-month studies in rats, using the lateral tail veins for injection. In dogs, almost any length of study should be possible; however, 3- or 6-month studies seem to be within the usual limits of practicability. If the drug must be given by slow injection rather than by bolus or slow push, there will be limitations on the numbers of groups and animals that can be used due to the equipment and increased technical staff needed to conduct such studies.

Mutagenicity

Mutagenicity studies are required for the marketing approval of new drugs. The role of mutagenicity studies in drug safety evaluation is sometimes misunderstood. The purpose of these studies is not to replace carcinogenicity

bioassays but to predict which drugs are likely to be positive in carcinogenicity bioassays and cause cancer in humans and to detect compounds that might cause hereditary germ-line mutations in humans. Such predictions require an in-depth knowledge of the mutagenicity assays available and scientific judgment. Sound predictions cannot be made strictly on the basis of numbers of positive or negative results in a few tests.

It is currently accepted knowledge that many, but not all, known carcinogens have the ability to cause damage to deoxyribonucleic acid (DNA). Such agents also have the potential to cause heritable germ line mutations. The mutagenicity studies currently available were designed to detect DNA-damaging agents. Positive results in these tests therefore indicate the possibility of carcinogenicity and germ cell mutagenicity resulting from the test compound. However, a negative result in mutagenicity tests designed to detect DNA-damaging agents does not imply that the compound will not be a carcinogen. We now realize that some carcinogens are nongenotoxic. Examples are the rodent liver carcinogens, phenobarbital and chlorophenothane (DDT), which are not mutagenic. These compounds are thought to cause liver tumors through their action as promoters. Bile acids are known to act as promoters in the induction of intestinal tumors. In experimental situations, certain compounds are known to act as cocarcinogens (enhancing the carcinogenic response only when applied concurrently with a DNA-damaging agent) or as promoters (enhancing the carcinogenic response when applied after the DNA-damaging agent). These types of carcinogens are not detected by mutagenicity assays. Currently, there are no short-term assays available for routine testing which reliably detect cocarcinogens or promoters, that is, nongenotoxic carcinogens.

Much publicity has been given to the absence of a high level of concordance among the results of a selected battery of four *in vitro* mutagenicity assays with the results of carcinogenicity bioassays in rats and mice (12). First, the number of compounds available for comparison is hardly an adequate sample size from which to make any general conclusions regarding the predictive capabilities of any series of assays. Second, the compounds selected for comparison of bioassays to genetic toxicity assays were heavily weighted in favor of genotoxic compounds. This makes the estimation of specificity for the mutagenicity assays (the ability to produce a negative result with a true noncarcinogen) difficult. Both sensitivity (the ability to produce a positive result with a true carcinogen) and specificity are used to determine concordance (the ability to produce a correct response with either a true carcinogen or a true noncarcinogen).

Furthermore, the compounds selected surely included compounds that were carcinogenic in the rodent bioassays but are not genotoxic. Finally, the four mutagenicity assays selected represent an artificial restriction on the comparison of mutagenicity assays to bioassay results. In practice, the genetic toxicologist is not restricted to using only a few specific assays.

As stated at the beginning of this section, certain mutagenicity tests are required by regulatory agencies for approval of new drugs. The ICH (International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use) (13) requires a battery of three categories of tests: (1) bacterial mutagenicity, (2) in vitro cytogenetics or in vitro mammalian cell mutagenicity assay with ability to detect chromosomal damage (i.e., mouse lymphoma tk [thymidine kinase locus] assay), and (3) in vivo test for chromosomal damage using rodent hematopoietic cells. For initial screening of new compounds, I recommend bacterial mutagenicity and in vitro cytogenetics. This is because the bacterial mutagenicity test, usually the Ames test using *Salmonella typhimurium*, is rapid, inexpensive, and sensitive. In vitro cytogenetics should be included because the bacterial test cannot detect agents that act at the level of the eukaryotic chromosome. Therefore, using these two tests, one can determine relatively quickly whether a new drug is a potent mutagen or not. If positive results are obtained in in vitro studies, other tests can be conducted to try to determine the mechanism responsible for the positive results, and to determine the potency and any specificity of the mutagenic response. If the drug is positive for mutagenicity in some tests but has relatively low potency, the drug might still be developed. In this case, in vivo mutagenicity tests may reveal a lack of detectable response. This would aid in defending the benefit/risk ratio for the drug. Some drugs may be positive in in vitro mutagenicity tests only in the presence of activating microsomal preparations. If this is the case, analysis of the metabolic products of the in vitro reaction may reveal that those products are not the same as the metabolites produced in vivo. Thus, the relevance of the in vitro mutagenicity study to in vivo risk assessment can be determined. The point is that one should not just accept in vitro study results at face value. Further study of positive results is usually warranted. Also, some of the mammalian cell in vitro mutagenicity assays are known to be sensitive to alterations in the osmolarity and/or the pH of the culture medium. Examples are the in vitro cytogenetics in Chinese hamster ovary cells and the L5178Y mouse lymphoma assays. The osmolarity in the assays should not be greater than 600 milliosmolar (14) and the pH should be in the range of 6.8–8.0 (15).

Several transgenic animal models are available for mutagenicity testing *in vivo*. The most widely used are the Big BlueTM and MutaTM Mouse models. These animals have portions of the *E. coli* galactosidase operon inserted into their genome. This bacterial DNA is used as the target for mutagenicity testing when the animals are treated with test chemicals. After chemical treatment, the bacterial DNA is removed from the tissues and packaged into bacterial viral (phage) particles. The phages are used to infect bacteria growing on agar plates. The bacteria multiply to form colonies that can be counted. Because of a color reaction that can be catalyzed by the galactosidase protein, a color reaction formed in the bacterial colonies can be used to assess the presence or absence of mutations formed in the target DNA from virtually any tissue within the treated mice.

Guidelines and protocols for specific mutagenicity assays can be found in Naismith, 1987; Brusick, 1980; Kilby et al., 1984; Mirsalis et al., 1994; Provost et al., 1993; and Heddle et al., 2000, listed in the Bibliography.

Reproductive Toxicity

Reproductive toxicology covers the entire process of reproduction from mating to pregnancy, birth, weaning, and, sometimes, the reproductive function of subsequent generations. The species most commonly used in these studies are rats and rabbits, although in special circumstances, other species such as mice, dogs, or monkeys are used. A series of studies is usually conducted so as to cover all the phases reproduction. Within each study, groups of animals corresponding to untreated controls and 2 to 3 drug-treated groups are used.

To assess potential effects on all phases of reproduction, separate studies are usually conducted that focus on distinct aspects of reproduction. The separate studies are usually designed to provide some overlap in the phases tested so as to avoid in gaps in the testing program. Fertility studies (historically called Segment-I studies) are generally intended to assess effects of the drug on the processes of spermatogenesis, oogenesis, mating behavior, copulation, fertilization, early embryonic survival and development, and implantation of the zygote in the uterus. Teratology (Segment II) studies are intended to assess effects of the drug on embryonic/fetal survival and development. Peri-/post-natal (Segment III) studies assess drug effects on late pregnancy, parturition, lactation, and postnatal development. One reason for dividing the reproductive process into phases is that, generally speaking, the shorter the treatment period, the higher the dosage that can be given without causing excessive toxicity. By dividing the reproductive process into shorter

phases instead of using the long phase required to encompass the whole process, higher dosages can be given to maximize characterization of the drug's toxicity in any part of the reproductive process. If a drug effect is found, the stage of the reproductive process affected by the drug can be more readily identified. This facilitates the assessment of risk for clinical use and helps the toxicologist design further studies, if needed, to examine the mechanism of action. A practical reason is that smaller studies can be conducted, sometimes in parallel fashion. Smaller studies allow flexibility in the timing of the evaluation of various parts of the reproductive process in accordance with the development program of a particular drug.

Fertility studies

Segment-I fertility studies are usually conducted in rats, although mice may occasionally be used. Rodents are used because of the convenience of housing large numbers of them, ease of mating, and widespread experience among reproductive toxicologists with these species. In these studies, the drug is usually administered to males for 28–30 days and to females for 14 days prior to mating. The duration of the spermatogenic cycle in rodents is approximately 60 to 80 days. However, a 28- to 30-day exposure period is considered sufficient to detect changes to the male reproduction when used in conjunction with thorough histological evaluation of the male reproductive tract. The treatment duration in females is considered sufficient to allow enough time for the females to be exposed to steady-state blood levels of the drug for at least a week to 10 days before mating. The animals are then placed with individual members of the opposite sex for mating. Treated males may be mated with treated females, or treated members of one sex may be placed with untreated members of the opposite sex. The females are observed for signs of mating, copulatory plug or sperm-positive vaginal smear, to determine mating performance. Generally, mating treated males to treated females is less costly because of the smaller numbers of animals involved. However, if drug-related effects are found, it may be necessary to repeat the study by mating treated animals with untreated animals. Drug treatment of the females is continued through the mating period and through mid-gestation. Treatment of the males continues until it is possible to determine whether there were any effects on fertility. If such effects are found, it may be desirable to remate the males to see if effects on fertility are reversible, or subject the males to histological evaluation of the reproductive tract to try to determine the cause of any fertility effects. Waiting until the end of pregnancy for the intrauterine examination offers the

advantage of an additional assessment for effects on intrauterine development. The fertility study may or may not be initiated prior to the IND application; however, it is usually required for the NDA. This fertility study in male animals is conducted prior to large-scale (phase III) clinical trials in men. This study is generally conducted prior to any clinical trials involving women of child-bearing potential. However, in the U.S. and Europe, women of child-bearing potential confirmed to be non-pregnant and using effective birth control may be enrolled in phase I and phase II (usually small-scale) studies prior to completion of the female fertility study.

Teratology studies

In teratology (historically called segment-II) studies, a drug is administered to pregnant animals during the period of fetal organogenesis. The studies are usually conducted in rats and rabbits, although other species such as mice or monkeys, are also commonly used. Most regulatory guidelines require that teratology studies be conducted on two species, and most suggest rats and rabbits as the preferred species. These species are used because of the ease of housing and handling, the ease of mating or insemination (rabbits), their short gestation period, and their large litter sizes (which facilitates statistical evaluation of the data). The period of drug treatment during gestation can be confusing. Most guidelines recommend gestation Days 6 to 15 for mice and rats and Days 6 to 18 for rabbits. Japanese guidelines recommend Days 7 to 17 for rats. These guidelines assume that the first day of pregnancy (the day when a vaginal plug or sperm in the vagina is found) is counted as gestational day 0. However, the guidelines of the Organization of Economic Cooperation and Development (OECD) recommend that if animals are artificially inseminated or pregnancy is determined by forced mating (rabbits are usually impregnated by one of these methods), the days of treatment be calculated by adding 1 day to the usual number. To accommodate all these guidelines, I recommend administering drugs during gestation Days 6 to 17 for rodents and Days 6 to 19 for rabbits. The extra day or two of dosing will have no adverse effect on the study but will allow compliance with worldwide guidelines.

At the end of the gestation, the dams are killed and the uteri examined internally for the presence of live, dead, resorbed, or degenerating fetuses. At this time the number of implantation sites and the number of corpora lutea are counted, and the internal organs of the dam are examined visually to detect any pathological changes that may have affected the pregnancy. The pups are weighed and examined for any external abnormalities. A number of the pups are fixed and prepared for examination of the

internal organs, and the rest are fixed and prepared for skeletal examination. In the case of rabbits, all the pups are subjected to both internal and skeletal examination. The abnormalities found are classified as either malformations or developmental variations. Malformations are those changes that are irreversible, alter general body conformity, interfere with body function or are possibly life-threatening, and are not commonly found in untreated animals. Variations are those changes that may be reversible, have no effect on body conformity or the health of the animal, represent slight deviations from the normal, and are found occasionally in untreated animals. Some changes, for example, reduced skeletal ossification or enlarged renal pelvis (apparent hydronephrosis), may simply be indicative of delayed intrauterine growth.

Dosages are selected so that some maternal toxicity is demonstrated during the study. This is to ensure a thorough test of teratogenic potential. It also has a practical application when the drug is used clinically. If during drug treatment a pregnant woman develops a toxic response, the physician is alerted to reduce the dosage or withdraw treatment. If it is known that the drug does not cause fetal toxicity or malformations at dosages up to those causing maternal toxicity, the physician can be assured that the fetus remains unharmed. If, on the other hand, a drug caused toxicity or developmental abnormalities in fetuses at dosages below those causing maternal toxicity, the physician no longer has the warning sign of maternal toxicity. With such a drug, the fetus may be harmed in the absence of maternal toxicity. Obviously, this is a more dangerous situation. Thus, the concept of toxicity to the adult mother versus the developing conceptus (or A/D ratio) assumes practical importance. Often, the results of reproductive toxicology studies are reported in terms of no-toxic-effect dosage for the dam and no-toxic-effect dosage for the fetus or offspring.

The special case of teratology studies in rabbits is worth mentioning. Rabbits are very susceptible to changes in the intestinal flora caused by some antibiotics. This usually leads to a marked reduction in food consumption, which leads secondarily to fetal toxicity, abortions, and fetal malformations. In such cases, the rabbit exhibits a species-specific sensitivity to the drug and may be an inappropriate species for a teratology study. However, the standard protocol may be modified so that the dams are treated with a drug for only a few days during the gestation period (e.g., Days 6 to 13 and Days 14 to 19, or smaller intervals). In this manner, excessive toxicity to the dam can be avoided while sufficiently high dosages of the drug can be given to provide an adequate test for teratogenicity.

The teratology study is often the first study of reproductive toxicity because it is less time- and resource consuming than are studies involving other phases of reproduction and because it assesses an end point, teratogenicity, which can have a major impact on further development of a drug.

Perinatal and postnatal toxicity

The perinatal and postnatal study (sometimes called a Segment III study) is usually conducted in rats. In this study, the drug is administered to pregnant rats from implantation (gestation day 6) through parturition and lactation. If desired, some of the fetuses can be taken at the end of gestation for morphological exams to satisfy the requirements for testing effects on organogenesis (teratology or Segment II phase). Effects of the drug on fetal development, parturition, nursing, growth, development, learning/memory, emotionality, and often, reproductive function of the pups are assessed. Postnatal developmental indices such as body weight gain, time of eye opening, pinna detachment, incisor eruption, vaginal opening, and development of righting and startle reflexes are evaluated. Some of the pups are retained after the lactation period for determination of behavioral variables such as learning, memory, and emotionality. Tests such as active or passive avoidance, shuttle box, and water T or M maze assess learning and memory. Test such as activity measurements or open-field behavior give some assessment of emotionality. In addition some of the pups may be retained for mating to determine the fertility and reproductive performance of the F1 generation. In this case, the study is usually terminated at the end of the F1 generation's pregnancy, but may be extended to assess early postnatal survival of the F2 generation. Again, the rationale is to conduct a stringent test for effects of the drug on development of the offspring.

Carcinogenicity Bioassays

Carcinogenicity bioassays are long-term studies conducted in rodents to assess the tumor-producing potential of a compound. These studies are conducted according to guidelines established originally by the U.S. National Cancer Institute. However, other guidelines, for example, OECD and FDA, are also useful in developing protocols. It is required that bioassays be conducted on both rats and mice over a period of time representing a majority of the natural life span for the species. Depending on the strain used, this is usually 2 years for rats and 18 months to 2 years for mice. The animals must be no older than 6 weeks at the initiation of treatment. The strains used are

most commonly Fisher 344 or Sprague Dawley rats and B6C3F1 or CD-1 mice. The animals are dosed daily, usually with orally administered drugs. If the drug is stable in the rodent's diet and can be mixed with it homogeneously, it is commonly administered via the diet because of the reduced staff required. Again, in the case of drugs, the concentrations of test compound in the diet are usually adjusted at regular intervals in order to maintain the target dosage level. The animals are examined frequently for the presence of palpable masses. Blood samples may be taken at 6-month or 1-year intervals for hematological evaluation, with particular attention paid to the development of leukemias. At the end of the study, surviving animals are killed and their tissues subjected to a thorough evaluation for the presence of neoplasia. The study design usually includes three drug-treated groups plus one or more control groups. The number of animals is usually 50 per sex for the drug-treated groups and 100 per sex for the control groups. However, extra animals (e.g., five per sex-group) are often started on treatment for the first 6 to 8 weeks of the study so that if animals die during the early phases of the study, which commonly occurs, there will still be enough animals on study to maintain the intended group sizes. The dosages are selected on the basis of the results of 3-month maximum tolerated dosage (MTD) studies. The object of the MTD studies is to determine the MTD for each sex of each mouse and rat strain to be used in the bioassay. The MTD is defined as a dosage that causes some degree of toxicity but not a decrement in body weight gain greater than 10% compared with that of controls; also, that does not cause toxicity, other than that related to a neoplastic response, which would be expected to shorten the animal's natural life span.

Recently, transgenic strains of mice have become available, which allow detection of a carcinogenic response within 6 months of treatment rather than 2 years. Examples of these are the P53 +/- (P53 knockout), TG.AC and the rasH2 mouse models. These animals contain deletions of genes involved in suppressing the formation of tumors. The use of these animal models is justified based upon the fact that these same genes are known to be involved in many human tumors. Thus, the mechanisms leading to enhanced tumorigenic response in these animals is known to be relevant to human tumorigenesis.

There has been controversy over the use of a maximum tolerated dosage in conducting carcinogenicity bioassays. The argument against the MTD concept is that the dosages usually required to satisfy the MTD criteria are unrealistically high relative to the exposure levels expected for the drug. Thus, a carcinogenic response at

the MTD would not be predictive of the same response in humans. However, it is my opinion that this high dosage is necessary to give a stringent test of the drug's potential to cause cancer. After all, we are trying to predict the response of a heterogeneous population with different susceptibilities to potential cancerogenic agents with relatively small numbers of homogeneous strains of animals. Even though we treat the animals for most of their lives, this is still only a 2-year period. Humans are potentially exposed to some drugs for much longer periods of time. We must, therefore, push the test system in order to understand the potential of the new drug. Nevertheless, there are cases where valid exceptions can be made. For instance, if the metabolism of the drug changes (different metabolites or kinetics are observed) at a particular dosage level, then the capacity of the organism to handle the drug in the usual manner has probably been exceeded. A carcinogenic response, or the lack of one, at dosages higher than that level would not be predictive. Obviously, if a drug is nontoxic, then a MTD may not be possible. If a drug causes alterations in levels of, or target organ responsiveness to, sex or thyroid hormones, high dosages may lead to tumor formation in animals secondary to the endocrine disturbances. If such disturbances do not occur below a certain threshold level, and if they are not expected at the human therapeutic dosage, tumors formed in a bioassay at higher than threshold levels will not be predictive of the risk to humans. The same argument applies if the drug stimulates cell division in the organs such as the liver of experimental animals. Such stimulation of cell division will likely lead to tumor formation in rodents. Again, dosages below those that stimulate cell division must be used for extrapolation of bioassay results to humans (16, 17).

The ICH guidelines allow several alternative ways of selecting the highest dosage for carcinogenicity studies in addition to an MTD. The highest dosage may also be selected based on dose-limiting pharmacodynamic effects, or systemic plasma exposure levels at least 25-fold higher than the human plasma. Certain pharmacodynamic effects if allowed to become exaggerated may affect the viability of animals on a study. Examples would be excessive hypotension with an agent that would be used to treat hypertension. In this case, excessive pharmacological action may lead to the death or poor condition of animals before the potential for carcinogenicity could be assessed. Other agents may cause behavioral changes. Dopamine agonists, for example, cause hyperactivity and stereotypical behaviors such as self-mutilating behaviors which, if allowed to become excessive, represent an issue in terms of humane, ethical treatment of animals. The 25-fold AUC criterion can be used only when there is no evidence for

genotoxicity. Under this condition, a dosage which gives a plasma systemic exposure level in terms of AUC (Area Under the Curve) that is 25 times higher than the maximal anticipated human systemic exposure is allowed even if toxicity is not produced. In this case AUCs of both parent drug and metabolites are considered, both individually and combined. In addition, the plasma exposures must be normalized for any differences in plasma protein binding between animals and humans. The "limit" dose concept can be used under certain conditions. There must be no evidence of genotoxicity, the human dose must be ≤ 500 mg/day, and the AUCs obtained in animals must be ≥ 10 times the human AUCs. If these conditions are met, the high dosage in a carcinogenicity study may be limited to 1500 mg/kg/day. Saturation of absorption means that at some point, if a higher dosage is given, no further increase in systemic exposure (plasma AUC) will be obtained. Under these conditions a dosage that is slightly above the dosage where the AUCs stop increasing with dosage will be accepted as the highest dosage. The maximum feasible dosage is limited by the amount of formulation that can be delivered safely to the animals without trauma (usually 10–20 ml/kg/day by oral gavage) or interfering with nutrition (e.g., 5% mixed in the diet). Other factors such as ability to prepare a homogeneous mixture with vehicle or diet or other physical characteristics of the compound or formulation may also be limiting factors.

The statistical analysis of bioassay results is sometimes controversial. Problems arise when early deaths occur and the distribution of such early deaths is not uniform among study groups. This is because in groups where more animals die early, the number of animals remaining at risk for the development of tumors over the remainder of the study is reduced. Thus, the probability of finding a positive result is artificially reduced for those groups. To overcome this problem, a method is commonly used whereby the entire study period is divided into small time intervals, and animals having tumors discovered at necropsy or tumors considered to have caused the death of the animal are compared among groups within the small time intervals. A comparison of the summation of tumor incidence rates within the time intervals is then used to determine if treated groups exhibit an increased incidence of tumors (18–20).

It is important to understand the situations and criteria that determine the need for a carcinogenicity bioassay of a new drug. If a drug is intended for long-term use, for example, some antihypertensive agents or benzodiazepine tranquilizers where the duration of exposure could be years or the remainder of one's lifetime, or if it will be available for widespread, uncontrolled use, then bioassays will likely be required. If the drug affects rapidly growing

tissues, for example, bone marrow or intestinal mucosa, or is known to affect cell division, bioassays may be required. If on the other hand, the drug is intended for short-term, controlled use, say, a few days, weeks, or months, and does not affect rapidly growing tissues, then bioassays will not be required unless mutagenicity tests indicate the drug represents a risk. If positive results have been obtained in one or more mutagenicity tests, the probability is high that a bioassay will be required. If positive mutagenicity results were obtained in *in vitro* studies only, and appropriate *in vivo* studies are negative, the probability of having to conduct a bioassay is much lower than if the *in vivo* studies are positive. In any case, I recommend holding discussions with the appropriate regulatory authority to determine the case for the particular drug under study. Currently, the cost for a set of bioassay studies in rats and mice is close to two million dollars. Therefore, the cost involved warrants a thorough mutagenicity program and meaningful interaction with regulatory authorities.

Immunological Sensitization

New drugs are sometimes tested for antigenic sensitization if they are suspected of being sensitizers. Such drugs would have a chemical structure similar to that of known sensitizers or would be high-molecular-weight compounds such as peptides. Agents to be administered topically are generally tested for dermal sensitization regardless of chemical structure.

Typical protocols for dermal sensitization, active systemic anaphylaxis, and passive cutaneous anaphylaxis tests are given in the article *Animals in Drug Development*, in this encyclopedia. In a typical gel-diffusion test, solutions of test compound, egg albumin (positive control), or vehicle (usually saline) are mixed with complete Freund's adjuvant. These mixtures are injected into animals (usually guinea pigs) of the respective treatment group once a week for 3 weeks. Two weeks after the last injection, blood is collected by cardiac puncture and serum (antiserum) is prepared. The gel diffusion is carried out on double immunodiffusion (Ouchterlony) discs containing trypan blue. Each disc contains a pattern of wells consisting of a circle of six 5-mm wells around a single 6-mm well. Antiserum is placed in the center well, and test compound or positive control or vehicle is placed in the wells surrounding the center well. The discs are incubated in a humidified 37°C incubator for up to a week to allow development of precipitation bands resulting from interaction between antigens (test compound or positive control) and antibodies (in antiserum). The precipitation bands are visible to the naked eye or with a dissecting microscope (21, 22).

Phototoxicity

Phototoxicity testing is not often included in the safety assessment of new pharmaceuticals; however, such studies may be conducted if phototoxicity is expected on the basis of reports on chemicals of similar structure or pharmacological class. Information on UV absorption spectrum of a compound may prompt phototoxicity testing. Sometimes reports of phototoxicity after a drug has reached the marketplace prompt laboratory studies of phototoxicity to determine if the drug is causing phototoxicity and, if so, by what mechanism.

Phototoxicity is to be distinguished from photosensitization (or photoallergy). Phototoxicity results from interaction of the drug or drug metabolites in the skin with light, usually in the UV region, to produce reactive molecular species that cause cell injury or death in the skin. Phototoxicity is most commonly produced under sunlight where the skin is exposed to the full range of UV light. The phototoxic response generally shows a dose response to both the amount of drug and the intensity or duration of light exposure. Photosensitization, on the other hand, results from an immunological response to by-products formed in the skin when the drug or its metabolites interact with light. The initial exposure to the drug and light may not result in an adverse reaction, but subsequent exposures to drug and light will result in an allergic reaction in sensitized individuals. The models described in this section are confined to the assessment of phototoxicity. Modifications of the models for dermal sensitization referred to in the section on immunological sensitization, incorporating light (i.e., UV light) as well as drug exposure, can be used to test for photosensitization.

Several sensitive and convenient models can be used to test for phototoxicity (23, 24). Guinea pigs, rabbits, and mice are the most commonly used species. Normal, albino guinea pigs and rabbits must be shaved or their hair removed with a depilatory before light exposure. Hairless mice have been used because of the obvious advantage of not having to remove the hair prior to testing. The euthymic, hairless guinea pig has also been used. These animals provide a convenient and sensitive model for phototoxicity testing (25). When conducting a phototoxicity test with normal animals, one finds that the hair can never be completely removed from the test site, and that this interferes to varying degrees with light exposure and scoring the resulting skin reaction. In addition, the ears, a site containing relatively small skin area, are sensitive indicators of phototoxicity. In some cases, the ears may be the only part of the animal where a skin reaction is obtained. With hairless animals, a much larger skin area is

available for accurate observation of the skin reaction. The larger size of the hairless guinea pig compared with that of hairless mice maximizes this advantage. With hairless animals, accurate scoring of skin reactions is facilitated because inevitably there will be an area where exposed and unexposed skin are juxtaposed along the sides of the animal. (This assumes the animal was exposed to light coming from above with the animal in the normal resting position on all four feet.) The comparison of the appearance of exposed and unexposed skin side by side in the same animal makes it easier to discern slight changes in skin appearance due to light exposure.

A test using the mouse tail has also been recommended for determining phototoxicity (26). In this test, mice of the same strain, age, sex, and weight are used. Groups of mice are exposed to the drug and UV light; after a period of 24–48 hours, depending on the drug, the tails are removed and the wet weight of the tails is determined. An increase in tail wet weight indicates an inflammatory response due to phototoxicity. Obviously, an untreated group as well as groups treated with only the drug or the light are included as controls.

In Vitro Toxicity

In vitro toxicity studies are being used more commonly in drug safety evaluation as improved techniques are being developed. Their main uses at present are as a tool for screening compounds for toxicity to particular cell types and in studying cellular mechanisms for target organ toxicity.

The most common assay systems consist of cell cultures that are treated with the drug in the culture medium. Toxicity is commonly assessed by release of intracellular enzyme, for example, lactate dehydrogenase or aspartate transaminase, into the culture medium or by other indicators such as decreases in the rate of radiolabeled amino acid or nucleotide precursor incorporation into macromolecules. A decrease in the intracellular uptake of the vital dye, neutral red, has also been used as a measure of toxicity with a variety of cell types. Fluorescent dyes are also available which allow, for example, estimations of intracellular Ca^{2+} concentrations, intracellular pH, or mitochondrial function. Such measurements can be helpful indicators of cellular toxicity and can help determine mechanism of toxicity.

An example of screening compounds for toxicity to particular cell types is the use of rat hepatocyte primary cultures in screening macrolide antibiotics for potential liver toxicity. The liver is a target organ for this class of compounds. In the development of new macrolides, this in vitro culture system is useful in discriminating those

macrolides that are more toxic to liver cells and those that are more toxic than other well-known and widely used antibiotics such as erythromycin. This information, together with data on antimicrobial potency and spectrum, acute in vivo toxicity, absorption, and so on, can be used to select new drug candidates for further development. The in vitro assay provides a rapid, sensitive means to simultaneously compare several compounds, using only milligram quantities of each drug. Such an in vitro system can predict only the inherent toxicity of the drug to hepatocytes. It cannot predict the modifying influences of the rate of absorption, distribution, and elimination that obtain in vivo. Hepatocytes used in such assays do have the ability to metabolize drugs to a limited extent. However, once the drug is placed into the culture medium, the cells are essentially exposed to that concentration of drug for the duration of the incubation period. Such prolonged exposure at the same concentration may not occur in vivo; therefore, the toxicity observed in vitro may not be predictive of the in vivo situation. The same arguments hold for other cell systems such as renal tubule cell, myocardial cell, or keratinocyte cell cultures. However, cell types such as the latter two have the additional limitation that they do not metabolize drugs as do liver or renal tubule cells. If the metabolite of a drug causes toxicity in these cell types, this would be missed in an in vitro assay unless some provision is made for introducing drug metabolizing enzyme systems into the assay.

Prescreening new compounds in in vitro tests for target organ toxicity can minimize the severity of toxicity and thus suffering and mortality in subsequent animal toxicity studies. Because fewer compounds will be tested in animals with this approach, in vitro tests will reduce the numbers of animals used in drug development.

To use such tests rationally, one needs to know the expected target organ for the type of drug under study. This knowledge may come from experience with similar drugs or from initial pharmacological or toxicological studies with a series of new drugs. Cell types such as the rat hepatocyte can also be used to study the mechanism of drug-induced hepatotoxicity. For instance, in addition to measuring the loss of intracellular enzymes, one could measure the amounts of intracellular glutathione, adenosine triphosphate (ATP), calcium, or enzymes of the various metabolic pathways to gain insight into possible mechanisms of toxicity.

Primary cultures of hepatocyte and tubule cells are prepared by collagenase perfusion and dissociation of the liver or kidney into cell suspensions. Primary rat myocardial cells can be similarly prepared by using trypsin to dissociate the cells. Rhythmic contractions of

myocardial cells can be observed in such cultures. Changes in these contractions serve as another end point for the measurement of toxicity (27). The L6 rat skeletal muscle myoblast cell line has been used to screen compounds for potential muscle irritating and damaging activity (28).

Newer technologies that use the methods of molecular biology are being applied to rapid screening of large numbers of compounds (high-throughput screening) for potential toxicity. These methods make use of knowledge of selected genes or patterns of gene expression that have been associated previously with toxic responses. The methods are known generally as genomics or proteomics. One approach is to expose cells, tissues, or an animal to a test compound and extract either RNA or proteins from the cells or tissue of interest. If RNA is extracted, DNA complementary to this RNA (cDNA) can be applied to a chip containing DNA from thousands of different genes to determine which of those genes are expressed in the drug-exposed tissues. This is determined by labeling the cDNA as it is formed with either radioactivity or a fluorescent molecule. The site on the chip where radioactivity or fluorescence is detected allows determination of genes that had expression levels either higher or lower than in untreated tissues. If protein is extracted, the protein extract is subjected to multidimensional gel chromatography to determine patterns of alteration in gene expression. These patterns are then compared to patterns previously shown to be associated with toxic responses in vivo with other compounds. Efforts are being made in some cases in the pharmaceutical industry to understand toxic responses in humans better by determining genetic susceptibility to adverse effects of specific drugs. Gene expression or genetic polymorphisms are studied in people who have had adverse reactions to the drug of interest. Once the genetic nature of the drug sensitivity is understood, other potential patients can be tested to avoid those who might be sensitive to adverse effects of the drug.

There are a few in vitro models available for rapid testing of ocular irritation potential. These tests were developed to minimize exposure of live animals to potentially distressing procedures. These include the BCOP (Bovine Corneal Opacity) test and the Eyetex test (29, 30). In the BCOP test, bovine corneas obtained from slaughter houses are treated under tissue culture conditions with solutions of the test compound to determine whether corneal opacity occurs. Corneal opacity is considered a type of severe ocular irritation. In the Eyetex test, the test compound is added to a solution of proprietary proteins. The protein solution is then observed for cloudiness or precipitation. Both these tests have a fair record of concordance with in vivo data.

Tests such as these are useful for rapid screening of large numbers of compounds or for preliminary testing prior to testing in animals. Compounds predicted to cause severe irritation presumably would not be tested further in animals.

In vitro systems have also been developed to use as screening tools or for mechanistic studies of teratogenicity. Among the most commonly cited examples are the limb bud assay (31) and the hydra assay (32). In the limb bud assay, cultures of mouse embryonic limb bud mesenchymal cells are prepared and exposed to test compound. Under normal conditions, the mesenchymal cells differentiate into chondrocytes. An agent that disrupts this differentiation process would be expected to be teratogenic. In the hydra assay, two protocols have been recommended. In both cases, the ratio of the test compound's degree of toxicity for the adult form of the organism to that for an undifferentiated form of the organism is the end point used to determine the relative teratogenic potential. In one protocol, the undifferentiated form is a mass culture of dissociated cells. In the other, it is the digestive region dissociated from the adult form. In both cases, the undifferentiated form will differentiate or regenerate the adult form unless inhibited by the test compound. Neither of these systems have found wide usage in new drug development. The hydra assay is probably better suited to screening environmental contaminants because of the economy of the assay and the massive number of environmental chemicals likely to be screened.

Immunotoxicity

Immunotoxicology is an area where refined methods of measuring functional changes in a particular organ system are increasingly being applied to the safety assessment of new compounds. The assays used for functional measurements are taken from methods used for research in immunology and for screening new compounds for in vivo antimicrobial or antitumor efficacy.

In routine subchronic-chronic toxicity studies, several variables are obtained that can be indicators of immunotoxicity. These include differential white blood cell count, spleen and thymus weights, histological assessment of spleen cellularity, and thymus and lymph node morphology. However, the new, more refined methods being applied to immunotoxicity assessment are more specific; they can indicate whether particular cell types or immunological functions are affected. These newer specific assays are not at present being applied on a routine basis to screen new drugs. Instead, they are applied selectively in cases where the particular drug is suspected

of being an immunotoxicant. This suspicion may arise from a structural relationship to previously known immunotoxicants (e.g., antivirals or steroids) or from data obtained in routine toxicity studies.

The National Institute of Environmental Health Sciences National Toxicology Program has recommended that immunotoxicity testing be done using a tier approach (33). Inbred strains of mice are usually used for these assays although methodology has been developed for conducting most of the assays in rats (34). The first tier would include those indicators routinely obtained in subchronic/chronic toxicity studies mentioned above, as well as specific assays for humoral-mediated, cell-mediated, and nonspecific immunity. In these specific assays, the animals are treated with a test compound for 14 days, for example, then their peripheral blood lymphocytes or spleen cells are used in the assay. The length of time for in vivo drug treatment will vary with the type of drug and its pharmacokinetics. The assay for humoral-mediated immunity consists of the plaque-forming cell assay to determine the numbers of splenic cells forming IgM antibody to a T-Cell dependent antigen (e.g., sheep red blood cells). In this assay, spleen cells from the treated animal are incubated in a mixture of complement and sheep red blood cells. The number of antibody-forming cells is determined from the plaques formed by areas of lysed sheep red blood cells on a background of unlysed red blood cells. The recommended assays for cell-mediated immunity are lymphocyte blastogenesis in response to a mitogenic stimulus (concanavalin A or phytohemagglutinin) and the mixed leukocyte response. In these assays, the extent of lymphocyte cell division is determined by incorporation of radiolabeled thymidine into cellular DNA after stimulation by a mitogen or by allogeneic lymphocytes, respectively. Natural killer cell activity is determined by incubating spleen cell suspensions from drug-treated animals with radioactive chromium-labeled target cells such as YAC-1 tumor cells. Release of free chromium into the culture medium is a measure of cell-killing activity.

The second tier includes assays that help determine the specific cell type involved in a response seen in the first tier and assays designed to assess the in vivo relevance of results seen in the first tier. These assays include quantitation of the numbers of splenic B and T lymphocytes, IgG humoral-mediated immunity, cell-mediated and nonspecific immunity, and host-resistance challenge models. Quantitation of B and T cells is done using cell-specific antibody techniques. IgG humoral-mediated immunity is assessed similarly to IgM humoral-mediated immunity (discussed above) except that a longer in vitro incubation time is used to allow the development

of IgG antibodies. Cell-mediated immunity can be assessed by the interleukin 2-dependent expression of cell-killer activity in a manner similar to the natural killer cell assay mentioned above. Nonspecific immunity can be assessed by counting the numbers of peritoneal macrophages in drug-treated animals and by measuring the ability of these macrophages to phagocytize radioactive chromium-labeled chicken red blood cells.

The host resistance models provide a means to directly assess the functional, and clinical significance of any changes found in the preceding tests. Direct assessment is important because of the multifactorial nature of immune responses and because of the well-known reserve capacity of the immune system. These assays consist of infectious agents or tumor cells that will routinely kill 10 to 30% of the animals not treated with drugs. An increase in the lethality of the challenge agent indicates suppression of the immune response. The challenge agent can be selected so as to challenge either humoral or cell-mediated immune systems.

SAFETY EVALUATION OF BIOTECHNOLOGY-DERIVED PRODUCTS

The safety evaluation of biotechnology-derived products is a developing area, which has been the subject of controversy. Safety evaluation has been developed for each product on a case-by-case basis. The ICH and FDA have developed guidelines for the safety evaluation of proteins and peptides produced via biological or cell culture systems (35). Several issues that should be addressed for each product have been identified (36, 37), through discussion among toxicologists concerning the appropriateness of applying the toxicity protocols used for synthetic pharmaceuticals to peptide products of biotechnology, and from examples of the few biotechnology-derived products that have been developed for clinical use.

Much discussion has arisen from the issue of potential contamination of the final dosage form by cellular material from the cell culture system used to produce the product. If a mammalian system has been modified by insertion of a DNA vector into cellular DNA, the concern would be over the potential contamination of the final product by transforming DNA. This might potentially increase the risk for developing cancer in a patient receiving such a contaminated product. For such products, assays for transforming activity of the final product or of DNA extracted from the cell culture system would be appropriate. The target limit for contaminant DNA that has generally been discussed is 10 picograms of DNA per

final dose. Assay for contaminant DNA should be established as a routine quality control procedure for production batches. Tests for transforming activity (e.g., cell transformation in C3H/10T 1/2 or Balb/c 3T3 cells) should be performed initially once the cell culture system is established and at periodic intervals to assure genomic stability of the cell culture system. Another source of problems with potential contamination is the antigenicity of the final product due to foreign cellular materials from the biological system used to produce the product, whether bacterial or mammalian. Also, with bacterial production, systems contamination with pyrogenic cell components must be avoided.

The development of neutralizing antibodies against a human protein that would be foreign to the test species is a major concern. The presence or absence of a neutralizing antibody must be determined in each test species used. This could very well limit the species that are appropriate to use in safety studies, and it could limit the duration of any toxicity studies conducted. Generally, neutralizing antibody titers could develop as early as 10 to 14 days after initiation of treatment. Therefore, for a product inducing such antibodies, toxicity studies of more than approximately 14- to 16-days duration would not be appropriate.

Knowledge of the product's pharmacological activity in the species used for safety testing is requisite for a valid toxicity study; obviously, this should be determined beforehand. The only toxicity induced by the product may be in the form of exaggerated pharmacological effects. Exaggerated pharmacological activity may arise through systemic exposure to a protein normally present in only small quantities at specific sites and/or through stimulation of nontarget receptors. In the latter case, if an inappropriate species is used, the safety of the product may be overestimated. Monoclonal antibody products represent a special case of this requirement. The species selected for testing a monoclonal antibody product should provide antigenic receptors for the antibody on the same target tissues as in humans. If the species selected has antigenic receptors that bind the antibody to unintended tissues, or if there are no antigenic receptors that bind the antibody, the results obtained from that species will be misleading and inappropriate. Generally, the closer in structure the product is to the natural product, the lower the need for extensive long-term toxicity studies; however, the greater the difference in structure between the biotechnology-derived product and the natural product, the more the situation comes to resemble that of a synthetic drug where more extensive toxicity studies are required. Improved predictions of human safety may be obtained through the use of transgenic animals bearing the human receptor. Alternatively, toxicity studies in animals may be

conducted using the animal homologue of the human protein under consideration. In addition, it may be possible to conduct studies in an animal model of the human disease. In these cases it should be demonstrated that the pharmacological response of the test system would be similar to the response in human tissues.

Much information can be gained from in-life physiological measurements such as blood pressure, electrocardiograms, body temperature, and respiratory rate. When the number of studies is reduced due to the lack of appropriate species and the potential for development of neutralizing antibodies, as much information as possible should be obtained from the few studies that are conducted. In-life measurements assume more importance in these cases. When the product is likely to contain proteins that may cause acute "serum sickness" type responses and pyrogens, measurements of blood pressure, body temperature, and respiratory parameters are especially important.

Local injection site irritation studies would be expected with these types of products because they are almost always given by injection.

Mutagenicity studies may be conducted if mutagenic contaminants are suspected. If a biotechnology-derived product is closely related to the natural product, there would be no need to conduct mutagenicity studies to assess mutagenicity of the compound per se. Carcinogenicity studies are not routinely needed for these types of products unless there is a concern about induction of tissue proliferation (e.g., with growth factors) or immunosuppression. Reproductive toxicity studies may or may not be conducted, depending on the nature of the product and its intended use. If the compound is suspected of having abortifacient actions (as with the interferons), a study in pregnant primates would be indicated.

USE OF METABOLISM AND PHARMACOKINETIC DATA IN DRUG SAFETY EVALUATION

There are a host of factors that can affect blood and tissue levels of a drug and thus affect exposure of target organs (38, 39).

Selection of the route of administration can affect the degree of absorption and time course of drug levels. The intravenous route can give a rapid rise and fall in drug levels following bolus administration or a steady level during slow infusion. Oral administration usually gives a slower rise and fall in blood levels than intravenous dosing does; however, the extent of absorption may be the same, that is, 100%. Intramuscular, intraperitoneal,

and subcutaneous administrations generally give rates of rise and fall of blood levels between those of intravenous and oral administration. If a drug is insoluble, or precipitates out of solution after injection, the intramuscular, intraperitoneal, and subcutaneous routes may give rise to a prolonged period of absorption from the injection site until all the drug has become solubilized and absorbed from the site.

For the oral route of administration, various factors such as the use of solutions versus suspensions versus dietary administration, the selection of the vehicle, the particle size, and the particle dissolution rate can affect the rate and extent of absorption. The absorption of a drug is likely to be greater if a solution rather than a suspension can be administered; on the other hand, the time course of rise and fall of drug blood levels is likely to be more prolonged with a suspension. There is some evidence that increasing the concentration of the suspending agent, for example, methylcellulose, can cause slower and less complete absorption. With dietary administration, the rate and extent of absorption are generally expected to be lower than with gavage dosing. Because rodents feed nocturnally, the period of drug consumption will be markedly prolonged compared with gavage dosing. However, because of the degree of dispersion necessary to prepare homogeneous dietary drug mixtures, and because of the long period available for drug administration, absorption from the diet can often approach 100% of that for gavage dosing. If a drug is intended to be administered several times per day, for example, over a 12-h period, dietary administration may provide the most appropriate means of modeling the expected human exposure. Particle size and the rate of particle dissolution can affect the rate and extent of drug absorption. The smaller the particle size, the greater the surface area per mass of the particle, and therefore the greater the rate of dissolution and absorption. The toxicologist has to be careful about using different batches of the same compound because the particle size may differ among batches. Such variation may affect the blood levels of a drug obtained in the test animals, which may in turn affect the toxicity observed.

For many drugs, most absorption probably occurs in the small intestine due to the vast surface area available. The rate of gastric emptying affects the delivery of drug to the small intestine. Therefore, the gastric emptying rate may affect the rate of absorption. The normal gastric emptying times are about 10 min for rodents, 30 min for rabbits, and 1.3 h for dogs. However, these times may be altered by drug administration, either pharmacologically or by the effect of variables such as dose volume or osmotic pressure. This further complicates the effect of gastric emptying on the absorption kinetics of the drug.

Oral absorption may be decreased as a percentage of administered dose at high doses. This can occur if the gastrointestinal transit time is less than the time required for complete absorption. This is sometimes the case with poorly absorbed drugs and drugs with poor solubility.

The selection of the vehicle can make a dramatic difference in the toxicity of a compound. An example would be the use of corn oil instead of methylcellulose to suspend a lipophilic compound. Corn oil may allow a better suspension, and possibly dissolve more of the drug, but it may also delay absorption of the drug due to retention in the lumen of the gastrointestinal tract. Opposite effects can also be obtained. I experienced a case where the toxicity of a drug was markedly greater when suspended in corn oil than when suspended in methylcellulose. In attempting to conduct intravenous studies with drugs having poor aqueous solubility, it is often necessary to use nonaqueous solvents, for example, ethanol, propylene glycol, or polyethylene glycol, to dissolve the drug. All nonaqueous solvents cause some degree of toxicity, whether cardiotoxicity, hemolysis, hepatic toxicity, or renal toxicity, that may complicate the toxicity assessment of the drug. Therefore, nonaqueous vehicles must be carefully selected, and the amounts and concentrations administered must be kept to a minimum.

The rate of intravenous injection can be a critical factor in determining the observed toxicity. Rapid administration of intravenous formulations will give high peak blood levels of drug, which may cause toxicity that could be avoided by infusing the drug at a slower rate. It is important in comparing the results of intravenous toxicity studies to note the injection rate. In designing a series of studies with a given formulation, it is important to use the same rate of injection. When determining upper tolerated limits for volume and rate of injection for a given species, knowledge of the glomerular filtration rate for the species can provide a useful guide. If one knows the rate of injection that will be used clinically, it is prudent to use the same injection rate in the animal toxicity studies. Interspecies differences in the rate and extent of absorption and in the metabolism of drugs are common and have a major effect on observed toxicity. Unfortunately, the toxicologist usually does not have this information when designing the initial toxicity studies. If the rat or dog is found to be an inappropriate species due to major differences in these parameters when compared to humans, some of the toxicity work may have to be repeated in another species. With some drugs, a large percentage may be metabolized to an inactive form by the intestinal mucosa or the liver before all the absorbed drug reaches the systemic circulation. This is called the "first-pass effect" because some of the active drug is removed

during the first pass through the mucosa or liver, which obviously decreases the effective or apparent absorption of the drug. On the other hand, if a large amount of the drug is given (e.g., at high doses in a toxicity study) so that the capacity of the first-pass metabolism is exceeded, the blood levels obtained will be disproportionately high and lead to excessive toxicity. It is important to be aware of any first-pass metabolism when designing oral or intraperitoneal toxicity studies. When a drug is administered intraperitoneally, most of the drug is absorbed via the portal circulation that flows through the liver before reaching general circulation.

When an active drug is excreted in the bile, it may be reabsorbed. This sets up a cycle of biliary excretion, reabsorption, biliary excretion, and reabsorption. Usually only a fraction of the drug is excreted in the bile, and only a fraction thus excreted is reabsorbed. Therefore, the cycle does not continue indefinitely when treatment is stopped. However, such enterohepatic recirculation can lead to higher blood levels of drug than would otherwise be obtained and can prolong the apparent blood or tissue half-life of the drug. Such a cycle can lead to alterations in the blood level-versus-time curve such that after a single dose the initial peak level is followed by a smaller peak caused by the reabsorption of excreted drug from the small intestine. This phenomenon can affect the blood levels and thus the toxicity obtained with a given dosage level, and should be taken into consideration when designing toxicity studies.

With substantial increases in body weight and in pregnancy, the volume of distribution will be increased since the blood and tissue volumes increase. The half-life ($t_{1/2}$) is directly related to the volume of distribution (V_d) as follows:

$$t_{1/2} = \frac{V_d \times AUC \times 0.693}{D}$$

where AUC is the area under the blood concentration-versus-time curve and D is the dose. With substantial increases in body weight, the $t_{1/2}$ for elimination increases also. The time required to reach a steady-state concentration of drug in blood or tissues upon repeated administration, or to eliminate virtually all of a drug after cessation of treatment, is roughly 4 to $5 \times t_{1/2}$. Therefore, the weight gain found in rodents during their phase of rapid growth (the first 3 to 5 months and during pregnancy) will have an effect on the time required to reach steady-state blood-tissue levels, and on the time required to clear a drug from the body.

The concept that four to five half-lives are required to achieve a steady blood level is also of practical importance when determining whether there is any accumulation of

blood levels over the course of a subchronic-chronic toxicity study. It is the usual practice to take blood samples early in the study and again toward the end of the study to determine if blood levels of the drug are higher at the end than at the beginning of treatment. If not enough time is allowed at the beginning of the study for steady-state blood levels to be obtained, the results may mislead one to conclude that accumulation has occurred. Similarly, if a recovery period is included in the study design, it is important to allow enough time for the drug to be eliminated from the test animals and to allow additional time for recovery from drug effects beyond that required to eliminate the drug.

Changes in the organs of elimination (e.g., liver and kidneys) can have dramatic effects on the blood levels of a drug, such that excessive blood levels and concomitant toxicity are obtained due to reduced elimination of drug. However, some drugs induce increased synthesis of metabolizing enzymes, mainly in the liver, and sometimes increased rate of bile flow. In these cases, lower-than-expected blood levels may be obtained. This may occur at higher dosages and after a period of time necessary to stimulate the metabolic machinery.

Many drugs are metabolized to products that have pharmacological and/or toxicological activity. The pharmacokinetics of these metabolites may differ from those of the parent drug, complicating the design and interpretation of toxicity studies.

EXTRAPOLATION OF ANIMAL TOXICITY DATA TO HUMANS

Continually present in drug safety evaluation are questions concerning the predictive value of toxicological findings in animals relative to those expected to occur in humans. Two questions are of importance: Will the same kinds of toxic changes occur in humans that occur in laboratory animals? At what dosage may toxic changes be expected in humans relative to the dosage in animals?

There are differences in the processes of absorption, metabolism, and excretion that have been identified between several laboratory species and humans (40). These differences are useful in the selection of the appropriate species in which to study particular compounds. However, having selected, as far as practical, the appropriate species, it is generally recognized that if toxic changes occur in more than one species, they can be expected to occur in humans as well. Predicting the kind of toxicity that will occur in

humans is usually less of a problem than predicting the dosage at which it will occur.

Generally, laboratory animals are less sensitive on a per body weight basis to the toxic effects of chemicals than are human beings. The sensitivity generally varies inversely with the size of the animals. More specifically, the sensitivity varies inversely with the surface area-to-body weight ratio. The surface area of a mammal is roughly the body weight raised to the two-third power. The ratio of the body surface area to the body weight determines the amount of energy that must be expended to maintain normal body temperature. The energy that is converted to body heat to maintain temperature is derived from the basal metabolic processes of the animal. The smaller the animal, the higher the metabolic rate because the ratio of surface area to body weight is larger. The rate at which drugs and other chemicals are metabolized and excreted generally varies with the basal metabolic rate of the species, which in turn varies with the surface area-to-body weight ratio. Thus, dosages comparable to a 1-mg/kg dosage in humans, after adjustment for differences in surface area, would be about 3 to 5 mg/kg for species such as rabbits, dogs, and monkeys, and about 10 mg/kg for rodents such as rats and mice. These factors are frequently used to establish the safe dosage for humans on the basis of animal toxicity studies. For example, the no-toxic-effect dosage obtained in a rodent toxicity study may be divided by 10 to determine the maximum dosage for clinical use in humans.

Application of the results of carcinogenicity studies to humans continues to be a controversial subject. Some of the issues involved were mentioned in the section on carcinogenicity bioassays. The relevance of tumors found at unrealistically high dosages is questioned as is the extrapolation of tumor incidence-dose response curves to low dosages where, presumably, no additional tumors above spontaneous incidence would be found. In some cases, as mentioned previously, where there is a clear change in metabolism or pharmacokinetics of the drug at high dosages, results found at such dosages may not be expected to occur in humans under normal, presumably much lower, exposure levels. The validity of the extrapolation of tumor incidence-dose response curves to low dosages where, theoretically, the tumor incidence should be zero, depends upon whether the compound acts as a genotoxic initiator or as a nongenotoxic promotor or cocarcinogen. Genotoxic compounds induce initiating, that is, DNA or chromosome damaging, events that can eventually lead to tumor formation. Nongenotoxic promoters or cocarcinogens can lead to tumor formation only in conjunction with the action of a genotoxic initiating compound. Promoters can act when applied

either at the same time as or after the application of the initiating compound. Cocarcinogens can act only when applied at the same time as the initiator. For most genotoxic compounds, theoretically, one molecule is sufficient, if it reaches the target DNA, to cause an initiating lesion. For promoters and cocarcinogens, it is generally understood that one molecule is not sufficient; there is a threshold concentration or dose below which the promoting or cocarcinogenic action is not obtained. Therefore, extrapolation to dosages below the threshold dosage would be appropriate for agents that act via promotion or cocarcinogenesis but not for genotoxic initiating compounds. An example of a class of compounds that cause DNA damage indirectly via interaction with a non-DNA target would be the topoisomerase inhibitors. Through inhibition of topoisomerase action DNA strand breakage normally caused by the enzyme is maintained, whereas without the action of the drug the breaks would be rejoined as part of the normal process of maintaining the DNA. The interaction of drug with the topoisomerase enzyme is subject to a dynamic equilibrium so that a certain concentration of drug is required to interfere with enzyme action. This drug effect, although causing DNA damage should demonstrate a threshold effect; since concentrations of drug below the critical level should be without biological effect (41).

Application of animal data on eye, skin, muscle, and vein irritation and pain on injection to humans merits comment. The rabbit eye is the most commonly used model for predicting eye irritation. This model is generally believed to be slightly more sensitive than the human eye to most irritants (42, 43). The same can be said for the rabbit skin as a model for human skin irritants. The muscle irritation test in rabbits seems to have a good correlation with clinical experience regarding painful intramuscular formulations even though this is not a test for pain (44). If a formulation causes muscle damage in rabbits, because of the similarity of muscle tissue across species, it can be expected to do so in humans. Vein irritation studies in animals are not always predictive of clinical results. If a formulation produces marked vein irritation in animals, it will likely do so in humans. However, a low level or absence of vein irritation in animals does not mean the formulation will not be irritating clinically. Several variables influence the irritating nature of an intravenous formulation. These are concentration of the drug, tonicity, pH, formulation ingredients other than the drug, rate of infusion, and number of repeated injections in the same site. Naturally, any changes in these variables between animal and clinical studies affect the predictability of animal vein irritation studies. Results of animal muscle

and vein irritation studies cannot be used to predict pain on injection in humans because pain is not an end point in these tests. The only available models for pain on injection, by any route, are the rat paw lick and mouse scratch tests mentioned previously. These seem to be predictive for the few compounds that have been tested for a correlation with clinical experience.

The application of data from reproductive toxicity studies to humans involves special considerations in addition to those mentioned above for general toxicity studies. This is especially true of teratology studies. The actual reliability of animal models to predict toxicity in this area is never known until adequate epidemiological studies are conducted in humans. Such epidemiological studies are rarely conducted due to the expense and time required. The ideal animal model would handle the drug (i.e., through absorption, distribution, metabolism, excretion, and maternal fetal distribution) identically to humans and would have the same maternal-placental-fetal relationships as humans. Because the animal models available to us rarely represent the ideal model, the best compromise is to test, for teratogenicity at least, in two or more species (45). If the drug causes fetal toxicity or teratogenicity in two or more species, it would be a good assumption that the drug will do the same in humans. Of the chemicals known to be teratogenic in humans, all but one class, the coumarin anticoagulants, are also teratogenic in at least one species of laboratory animal, (46). However, there are many chemicals known to be teratogenic in animals that are apparently not teratogenic in humans. This may be due to lower levels of exposure in humans or to more careful management of exposure as in the case of pharmaceuticals. Animal models have greater predictive power when combinations of two or more species are used. Among the species commonly used for teratogenicity testing, rats and mice seem to be the best for modeling human responses. However, the use of rabbits in combination with either rats or mice provides greater predictability because rabbits are less likely to yield false positive results. The rabbit was originally selected as a second, nonrodent species for routine teratogenicity testing because of its responsiveness to thalidomide.

Finally, it should be pointed out that although the animal models commonly used can predict the fetal toxicity of a drug in humans, the exact type of fetal toxicity in humans cannot be predicted. If an agent causes fetal toxicity of any kind in animals, it should be suspected as a potential human teratogen or fetal toxin. Valproic acid serves to illustrate this concept: It causes skeletal abnormalities in rats and rabbits. In humans, it has been shown by epidemiological studies to cause a low incidence

of spina bifida, a neural tube defect. Therefore, the type of fetal toxicity caused in the animal models may differ from that caused in humans, but the fetal toxicity in humans could be predicted from the animal studies. It turns out that valproic acid also causes neural tube defects in mice and hamsters. In summary, the animal models used for teratogenicity screening seem to provide reasonable predictability for fetal toxicity in humans. The greater the number of species with positive results, the greater the likelihood that the drug will also cause fetal toxicity in humans.

Dry Powder Aerosols: Emerging Technologies

Nora Y.K. Chew
Hak-Kim Chan

University of Sydney, Sydney, New South Wales, Australia

INTRODUCTION

The delivery of pharmaceutical aerosols as a dry powder is no longer perceived as the “second best” method to deliver drugs to the lung. This is because of the mounting technologies, which are capable of making stable powders of respirable size and devices competent to deliver accurate doses and versatile payload.

The identification of the lung to deliver drugs to the bloodstream has expanded the kinds of chemical entities that can be delivered via this route. Therapeutic proteins and polypeptides such as insulin administered as a powder via the lung are examples showing substantial systemic absorption into the bloodstream, resulting in well-controlled blood glucose level for diabetes.^[1,2]

The delivery of therapeutic macromolecules by inhalation, however, presents additional problems and challenges to produce fine powders of particle size 0.5 μm –5 μm that flow well during manufacture, filling, and emptying from the inhaler device. Macromolecules are more “fragile” compared with small molecules, thus imposing certain restrictions during manufacture and storage in order to maintain not only their dispersibility, but also their biochemical and physical stability. Proteins and polypeptides are often substantially more expensive than the small molecules; therefore, the ability to efficiently deliver the dry powder with minimal loss is crucial. Furthermore, adequate dispersion and delivery of the powder to the patient are especially important for reproducible lung distribution and systemic absorption of drugs.

This review captures some of the most recent technologies with examples relating to pharmaceutical dry powder aerosol delivery.

EMERGING TECHNOLOGIES FOR POWDER AEROSOL DELIVERY

Two main areas that have been given most attention to improve inhalation drug delivery of powders are: (I) powder production and formulation and (II) powder inhaler devices.

Powder Production and Formulation

Traditionally, freeze-drying has been the process used to produce dry powders of proteins and peptides from a solution. This is because the solution can be dried without being exposed to elevated temperatures, which may adversely affect the product stability. Unfortunately, powders prepared by this method are too large in size for inhalation. Even though milling of the freeze-dried powders to reduce particle size is feasible, the pressure, temperature, and shear resulting from milling may cause significant loss of bioactivity of proteins.^[3,4]

To date, the two most successful ways for making powders for inhalation are spray drying and solvent precipitation.

Spray drying

Spray drying involves converting the atomized liquid droplets into dry powders by hot air. This one-step process is capable of making particles of size suitable for inhalation.^[5] The particle size and size distribution of the powder can be manipulated by the concentration of the feed solution, the spray temperature, cyclone efficiency, and chemical nature of the feed.^[6]

Therapeutic proteins prepared as dry powders are often found unstable when dried alone. Due to the tremendous surface area of the atomized droplets and the relatively high drying temperatures and mechanical stress during atomization, the integrity of the protein may be adversely affected during spray drying. Protein degradation can be minimized by cospray drying the protein with excipients as has been reported for recombinant human deoxyribose nuclease (rhDNase) for inhalation.^[7,8]

Molecular aggregation of recombinant human growth hormone (rhGH) due to air–liquid interfacial degradation can be prevented by adding polysorbate-20 (with no sugar protectant) or Zn^{2+} into the liquid feed. Polysorbate-20 significantly reduced the formation of insoluble protein aggregates, while Zn^{2+} suppressed the formation of soluble protein aggregates. Combination of polysorbate-20 and Zn^{2+}

resulted in a spray-dried rhGH powder having insignificant protein degradation. The occupancy of polysorbate at the air–liquid interface of spray droplets and the formation of a dimer complex between Zn^{2+} and rhGH are believed to reduce the chance for protein unfolding and aggregates formation.^[9]

Spray drying of recombinant humanized monoclonal antibody, anti-IgE (rhMAbE25) containing trehalose or lactose had $\leq 1\%$ of aggregates formed following spray drying.^[10] Despite that, the powders containing trehalose were too cohesive for aerosol delivery. Mannitol was less capable of stabilizing rhMAbE25, with 1%–3% aggregates found following spray drying. The stabilizing effect of mannitol leveled off at a mannitol concentration of ~ 20 wt. %.^[11] In the case of follicle stimulating hormone (FSH), formulation containing mannitol, sucrose, and raffinose as excipients gave rise to $\leq 2\%$ of the higher order aggregates formed from spray drying. Mannitol-containing formulations had the highest amount of aggregates (1.2%) than those of sucrose and raffinose (0.05%). The production yield of powders from the mannitol-containing formulation (50%) was much less than that of sucrose (79%) and raffinose (74%). Despite these, the mannitol-containing formulation has the highest emitted dose of 66 wt. % vs. 15 wt. % and 55 wt. % obtained from the sucrose- and raffinose-containing formulation, respectively.^[12] These results indicate that each protein/excipient system requires individual characterization to identify an optimal formulation for powder aerosol performance and protein stability.

Modification of the spray drying process

Spray Freeze-Drying. Spray freeze-drying, a method developed for producing protein aerosol powders, involves spraying the feed solution into liquid nitrogen followed by freeze-drying. This process produces large ($\sim 8\text{ }\mu\text{m}$ – $10\text{ }\mu\text{m}$) but porous particles of rhDNase and anti-IgE with high production yields ($> 95\%$). The fine particle fraction (FPF) of the spray freeze-dried powder was significantly higher than that of the spray-dried powder due to improved aerodynamic properties.^[13] The overall process, however, is much more costly, time consuming, and complex as compared with spray drying.

Process for Spray Drying Hydrophobic Drugs. The conventional spray drying process is usually limited to hydrophilic drugs with hydrophilic excipients in aqueous solutions. It is not feasible for systems containing hydrophobic drugs and hydrophilic excipients or vice versa. While spray drying of hydrophobic materials can be accomplished using an organic solvent, a patented invention

has been developed for spray drying pharmaceuticals and other compositions, which comprise both hydrophobic and hydrophilic substances. A basic requirement is that the hydrophilic excipient and hydrophobic drug would be at least partially dissolved in the same organic solvent or cosolvent system.^[14] For example, both budesonide (hydrophobic drug) and povidone (hydrophilic excipient) have high solubility in methanol. Such a drug/excipient composition yielded powders of slightly dimpled spheres, with moisture content of 0.49 wt.%, and particle size of $2.3\text{ }\mu\text{m}$. The delivered dose efficiency was measured as ~ 50 wt.%. The use of a nonaqueous or partially aqueous system has the advantage of preparing powders that are physically or chemically sensitive to water while in solution or to residue moisture in the powder.

Solvent precipitation

The solvent precipitation method utilizes the unique properties of nonsolvent at a critical temperature and pressure to precipitate solid particles of drugs from solutions. Carbon dioxide, which exhibits remarkable solvent power at its critical temperature of 31.1°C and pressure of 70 bar for high molecular weight and low vapor pressure solids, is an ideal nonsolvent choice. CO_2 is also nontoxic, inexpensive, and readily available. Technical details of supercritical fluid technology can be found in Vol. 18 of this encyclopedia series.^[15] The technology has been successfully applied to the production of fine particles for aerosol delivery.^[16–18]

York and Hanna^[17] have developed the SEDS (solution enhanced dispersion by supercritical fluids) process for preparing powders of an anti-asthmatic drugs salmeterol xinafoate. The method is capable of controlling the dispersion of the solution in the system, and thus has the ability to manipulate the characteristics of the particles in the micrometer-sized range. This technique has also been used to prepare powders of therapeutic proteins, with the key experimental component being the three-channeled coaxial nozzle designed to use high velocity supercritical CO_2 to disperse the feed of aqueous and organic nature into the particle formation vessel. Relatively high percent of bioactivity was maintained for lysozyme and a therapeutic peptide (95% and 100%, respectively).

Alternatively, protein particles can be produced using a supercritical or near critical CO_2 -assisted aerosolization and bubble drying process.^[20] This method utilizes the high solubility of CO_2 in water, coupled with expansion of the solution through a nozzle to aerosolize aqueous solutions of drugs. When the microbubbles formed are dried, solid (such as lactose and albuterol sulfate, with size between $0.5\text{ }\mu\text{m}$ and $5\text{ }\mu\text{m}$) or hollow spherical particles (such as sodium

chloride, mannitol, or tobramycin sulfate) are formed depending on the compound. Protein powders such as lysozyme or lactate dehydrogenase can also be produced by this process and can be stabilized through the use of sugars, buffers, and surfactant additives in the formulations. Depending on the solute and conditions of drying, the particles are crystalline in some cases and amorphous in others.^[21]

Recently, Bustami et al.^[22] have investigated the feasibility of the ASES (aerosol solvent extraction system) process to generate microparticles of proteins for inhalation. Protein powders generated were of particle size 100 nm–500 nm. In vitro performance showed 65, 40, and 20 wt. % respirable fraction for lysozyme, albumin, and insulin, respectively. Little or no loss of monomer content was observed for these proteins.

Ways to improve powder flowability and dispersability

Inclusion of Excipient. Powders prepared by any one of the above methods may not be used directly as the powders may be too cohesive for device filling and for administration as an aerosol. This is the case for anti-IgE cospray dried with trehalose^[10] and spray-dried rhDNase powders.^[8] In contrast to the traditional approach of using binary blend systems (i.e., drug plus coarse carrier), the addition of fine carrier particles ($< 10\ \mu\text{m}$) such as lactose and magnesium stearate to form a ternary system has been shown to further enhance the amount of drug particles in the aerosol cloud.^[23,24] The role of the fine carrier particles is believed to reduce the drug–coarse carrier interaction by occupying possible drug binding sites on the larger carrier particles. The formation of multiplets between the fine carrier and drug may hinder the direct contact between the drug and the coarse carrier, thus promoting detachment of drug particles from the carrier surface during powder dispersion. Magnesium stearate at concentration as low as 0.1% was found to be sufficient to increase the fine particles of salbutamol sulphate in the aerosol cloud.^[24]

Recently, Ganderton et al.^[25] have found that the inclusion of low-density amino acid particles produced by spray drying can also enhance the amount of fine particles in the aerosol. Such low-density, flake-like particles have a bulk density of 0.1 g/mL with thickness of $\leq 100\ \mu\text{m}$ and $\text{MMAD} \leq 10\ \mu\text{m}$. Addition of low-density leucine particles as low as 1% enhances the fine particles of salbutamol in the aerosol by $\sim 25\ \text{wt. \%}$. However, the addition of 10% leucine made no difference to the amount of fine particles in the aerosol compared with salbutamol alone.

Another conventional approach to improving powder flow and dispersion is to form agglomerates. However, liquids that are commonly used, e.g., alkanols, may dissolve

and denature the actives such as macromolecules. The recent discovery of fluorocarbon (FC) liquids including perfluorodecalin and perfluorooctyl bromide as alternatives may be useful because they are hydrophobic and do not dissolve proteins. In addition, FC has a low surface tension; relatively weak bonds are expected to form between the fine particles of the loose agglomerates, which can be then redispersed readily as an aerosol. The high vapor pressure of FC renders low solvent residue in the final product.^[26] Fluorocarbon does not contain chlorine atoms, and is therefore ozone friendly.

Tailor-made powders

Besides the use of excipients, powder flow and dispersion can also be improved by manipulation of the physical characteristics of the powder.

AIRTM Particles. AIRTM particles (Alkermes, Inc., Cambridge, Massachusetts, U.S.A., Fig. 1) are prepared by spray drying solutions containing a mixture of drug and biodegradable material (e.g., polyglycolic acid, polylactic acid, or copolymers). AIRTM particles have a low tapped density of less than $\sim 0.4\ \text{g/cm}^3$, with an irregular surface. These low-density particles are physically large but aerodynamically small, which enhances the flow and dispersion of powders, and are ideal for deep lung delivery. Large particles could also minimize phagocytic uptake in alveoli, thereby providing the potential for controlled release of drugs in the lungs.^[27,28]

PulmosphereTM. PulmosphereTM (Inhale Therapeutic Systems, San Carlos, California, U.S.A.) particles are also prepared by spray drying, in which the feed

Fig. 1 AIRTM particle. (Courtesy of Alkermes, Inc., Cambridge, Massachusetts, U.S.A.)

comprises an aqueous solution containing dissolved or dispersed active drug, and a fluorocarbon-in-water emulsion, stabilized by a monolayer of phospholipid (such as dipalmitoylphosphatidylcholine).^[29] Being hollow and porous, Pulmosphere™ particles have a bulk density of 0.05 g/cm^3 – 0.2 g/cm^3 , and a size between $2 \mu\text{m}$ and $4 \mu\text{m}$. These particles are dispersed more readily without the need of carriers than the traditional drug–carrier blends with lactose.

Wrinkled Surface Particles. In contrast to the AIR™ particles and Pulmospheres™ which are hollow and porous, *solid* protein particles with wrinkled surfaces have recently been prepared in our laboratory. These wrinkled particles gave a significant improvement in FPF over spherical particles of bovine serum albumin.^[30] The reduction of the surface contacts among the wrinkle particles (Fig. 2) is believed to reduce powder cohesion. Dispersion of the wrinkle particles was shown to be less dependent on the inhaler choice and airflow compared with the smooth spherical particles of the same aerodynamic size.

Powder Inhaler Devices

Dry powder preparation and formulation are only part of the inhalation drug delivery system. Dispersion of these powders is closely linked to the performance of the inhaler device.

Recent inventions of the powder inhaler device are aimed at improving the inhaler's dispersion efficiency and reducing the resistance of the device as well as

Fig. 2 Wrinkled bovine serum albumin particles, produced by spray drying.

decoupling powder dispersion from the patient's inspiratory effort in order to deliver accurate and flexible dosages for different patient's needs.

Innova™ and Solo™

The Innova™ (Inhale Therapeutic Systems, San Carlos, California, U.S.A., Fig. 3) inhaler device is a unit dose inhaler that has been designed for long-term use. It is powered by a stored bolus of compressed air and is designed to generate aerosol independent of patient's inspiratory effort. A transparent holding chamber enables patients to view

Fig. 3 Schematic diagram of Innova™ from Inhale Therapeutic Systems. (Adapted from Ref. 32.)

the aerosol to assure proper dosing. Further, the device is designed to have the capability to fluidize and extract up to 90% of the dose from the reservoir, thus minimizing waste and enhancing the accuracy and precision of the dosage.^[31]

The Solo™ device from Inhale Therapeutic Systems is a patient-driven unit dose inhaler. It has a built-in flow control to maximize the reproducibility of dose to patient. It is designed for short-term use and when large drug dosages are preferred.^[32]

SkyePharma mDPI

SkyePharma multidose pocket-sized inhaler features an “intelligent” single dose counter to count the dose dispensed and remained in the inhaler. The built-in locking mechanism also allows no “tailoff” effect toward the last doses from the inhaler^[33] (Fig. 4).

Bead inhaler technology

Elan Pharmaceuticals has developed the Spiros® S2 inhaler which features the use of beads to disperse the powders on inhalation. Still under development, the results from testing show that Spiros® S2 is a high dispersion efficiency inhaler capable of delivering drugs at relatively low inspiratory flow rates (30 L/min and 60 L/min).^[34]

Twisthaler®

The Twisthaler® (Schering-Plough, Kenilworth, New Jersey, U.S.A., Fig. 5) features specially designed nozzle

Fig. 4 SkyePharma mDPI. (Courtesy of SkyePharma, PLC, Switzerland.)

Fig. 5 Inhalation through the ASMANEX™ TWISTHALER™ DPI. (From Serentec Press, Raleigh, North Carolina.)

geometry that creates an airflow pattern which carries the small particles out of the device via the fluted chimney, while the larger particles or agglomerates will be spun into a centrifugal pattern and deagglomerated into fine particles for inhalation. The design optimizes the deagglomeration of powders, but at the same time minimizes drug caught in the inhaler nozzle and mouthpiece.^[35]

Hovine FlowCaps®

Hovine FlowCaps® (Hovione SA, Loures, Portugal, Fig. 6a and b) is a capsule–powder inhaler. Instead of the traditional needle piercing, the capsule is pierced by two blades, giving rise to a narrow slit across each end of the capsule. The tube-shaped inhaler receives the capsule(s) at one end.^[36,37] Upon inhalation, the air is mainly entrained into the inhaler tube inlets, with only a little air entering the capsules. The powder gets fluidized and experiences turbulence within the capsule before emptying from the device.

Random Loading

Capsules do not have to be inserted in a proper orientation, as in all other capsule based systems.

A patented ramp will automatically right a capsule for loading into the inhalation chamber. The patient can visually check that this is happening.

Ease of use is fundamental for patient compliance.

Drug Master Files

C. Jeanne Taborsky
Brian James Reamer

SciRegs Consulting, Columbia, Maryland, U.S.A.

INTRODUCTION

In most cases, in order to market a new drug or generic drug in the United States, the manufacturer must file a drug application with the Food and Drug Administration (FDA). The FDA must review and approve the drug application. In support of the application, the manufacturer can reference the information that is filed with the FDA in a Drug Master File (DMF). This information is confidential and the technical contents of a DMF are (usually) only reviewed when authorized by the DMF holder and reviewed only in connection with the review of an Investigational New Drug (IND), New Drug Application (NDA), Abbreviated New Drug Application (ANDA), or an Export Application. A company that intends to conduct a clinical investigation on an approved drug must file an IND. A drug company that wants to market a new drug or a previously approved drug in a new container or a new formula must file a NDA. A company that wants to market a generic drug must file a ANDA. A company that wants to export a drug that is not approved for marketing in the United States must file an Export Application submitted under Section 802 of the Federal Food, Drug, and Cosmetic Act. The DMF is a critical part of the review process and is in increasing use. For this reason, many drug applicants will not use a supplier who does not have a Drug Master File. Drug Master Files are not accepted or rejected, but are rather found to be satisfactory or deficient in support of the drug application in which they are provided. Marketing a pre-1938 drug or a drug for which an Over The Counter (OTC) Monograph status has been granted does not require the filing of an application with the FDA.

FDA—ORGANIZATION

The FDA is divided into different centers, each with their own set of regulations and areas of responsibility.^[1] These centers and their areas of responsibility are as follows:

- CSFAN—The Center for Food Safety and Nutrition: Responsible for regulating foods, dietary supplements, and cosmetics.

- CBER—The Center for Biological Evaluation and Research: Responsible for regulating biologics, blood.
- CDRH—The Center for Devices and Radiological Health: Responsible for regulating medical devices, kits, and diagnostic solutions.
- CVM—The Center for Veterinary Medicine: Responsible for regulating animal medicine.
- CDER—The Center for Drug Evaluation and Research: Responsible for regulating drugs.

Drug applications filed with the CDER can be for INDs, NDAs, and ANDAs, also known as generics.^[2] The CDER, the CBER, and the CVM share access to the same Drug Master Files.

The CDRH does not use DMFs submitted to the CDER, and submissions to the CDRH are not reviewed or used to support drug applications to the CDER. This aspect of the drug review and approval process is important because there is an overlap of responsibility in the use of some materials and components regulated by more than one center. A syringe that is sold on its own merit, without an associated drug, is regulated by the CDRH, while a syringe containing a drug is reviewed by the CDER. There is an internal FDA intercenter agreement that details the divisions of authority. The CDRH would only comment on a component if requested by the CDER reviewer. Therefore filing information to the CDRH on a syringe does not obviate the need to file a DMF to the CDER. The CDER has defined the information that they expect to review in support of a drug application, and the information should appear in the drug submission or a referenced DMF.

DRUG MASTER FILES

A Drug Master File (DMF) is a submission of information to the FDA by a person or a firm.^[3] A DMF is filed with the intent to permit a drug applicant to use (incorporate by reference) the information contained in the DMF in support of a drug application or a supplemental change to an approved application without having to disclose the information to the drug applicant. Drug Master Files were originally used as a way for suppliers to file limited confidential or proprietary information with the FDA in sup-

port of the drug application, while keeping the information confidential from the end user and the competition. In the United States, confidentiality is still an important aspect of the process. In Europe, the relationship between the DMF holder and applicant are somewhat different: It is not uncommon for the DMF holder to provide a copy of the Drug Master File to the drug applicant or customer.

Although firms have the option of filing their own DMF or providing the information to an applicant to file in their drug application, there are many disadvantages to having the drug applicant file the information. The holder of the intellectual property would have to confide the information to the applicant, thereby losing control of it. The term "control" does not refer only to confidentiality of the information, but also to document control: The tracking and update of changes. For multiple drug applications, the information is repeatedly reviewed for each drug submission. Different reviewers may have different questions based on their areas of expertise or the end use of the material. Therefore the information may be rereviewed with questions and responses repeatedly filed to each individual drug application. Filing DMF-type information in the NDA or ANDA significantly increases the size of the drug submission, and increases the workload for the FDA reviewer. The information must be well controlled and updated with all drug applicants whenever a change occurs. With a DMF, the information is reviewed once, and if found satisfactory, may not be reviewed for 2 years, unless the end user is changed or the information is amended. A record of the satisfactory review is maintained in the FDA computer database and filed in the Drug Master File. The DMF holder does not receive a copy of the review and is only contacted by the FDA if the DMF is found to be deficient.

DRUG MASTER FILE PROCESS

Two copies of the Drug Master File are mailed to the Drug Master Files Staff, located at 12229 Wilkins Avenue, Rockville, Maryland 20852.^[4] The Drug Master File staff will audit the nontechnical information for completeness and adequacy for submission. If the key elements are missing, the staff will contact the proposed holder to try to obtain the necessary documents in order to file the DMF. Once the DMFs are determined to be acceptable for filing, the document room staff assigns a DMF number and a letter is sent to the contact person listed in the DMF.

DRUG MASTER FILE FORMAT

The DMF must meet the format requirements.^[5] The DMF is submitted as Original and Duplicate jackets,

Fig. 1 DMF jackets.

collated, assembled, paginated, and jacketed, using covers obtained from the government printing office. Multiple volumes are numbered, and the paper must be standard U.S. size paper. It is not unusual to receive paper from England or India that is of different size or weight. Because the pages are placed in binders, the left margin should be no smaller than 3/4 in. and the right margin should be no smaller than 1/2 in. The DMF must be submitted in two copies, one with a blue cover and one with a red cover. The jacket covers are purchased from the government printing office and are specifically provided for the DMFs (Fig. 1).

REQUIREMENTS

The regulations for Drug Master Files are listed in the *Code of Federal Regulations* Title 21 § 314.420. In addition, the CDER has issued guidances to better describe the format and provide some suggestions on content. These guidances can be found on the CDER guidances web page www.fda.gov.

A DMF provides (incorporates) information by reference and permits the "holder" to "authorize" other "persons" to disclose information in support of an application. Usually, a DMF may only be accessed (reviewed) by the FDA if the holder of the drug application provides the FDA with authorization (by incorporation), in writing, with two copies, dated, with the DMF number, name of holder, name of material, specific product, reference number/volume, page number, name of authorized persons, and a statement of commitment that the DMF is current. The letters filed to the DMF must have the original signature, typed name, and title of the authorizing person on the letterhead. A copy of each letter is provided to the drug applicant to file in their submission.

The applicant is not required to acquire a new letter for each submission. The DMF holder usually does not know for which drug an applicant has filed their DMF letter. Regulations governing DMFs are very general. For all DMFs, the following must be provided: The names and addresses of the DMF holder, the corporate headquarters, the manufacturing/processing facility, as well as the name, address, phone number, and fax number for the company contact for FDA correspondence, and the contact information for agent(s), if any. The specific responsibilities of each person listed in any of the above categories should be listed. Including an organization chart with job titles helps to communicate this information. A statement of commitment is required, as well as a signed statement by the holder certifying that the DMF is current, and that the DMF holder will comply with the statements made in the DMF. The commitment letter, a letter appointing the U.S. agent, and any debarment or current Good Manufacturing Practices (cGMPs) statements should all be provided on separate pages.

When a U.S. agent is “appointed,” the DMF holder should submit two copies of a letter to the DMF giving the agent’s name, address, and scope of responsibility (administrative and/or scientific). Drug Master File holders are not required to appoint an agent, but foreign DMF holders are encouraged to do so. The holder or agent is required to submit archival and duplicate copies and notify each person authorized to incorporate information of changes, additions, or deletions. It should go without saying that the holder must conform to the procedures listed in the DMF.

The DMF should include the name, address, phone number of holder, a description of items that are the subject of the DMF, a list of materials of construction, and the sources of materials of construction. The standards for testing incoming, in process, and release are sometimes different. There are five types of CDER Drug Master Files listed in the *Code of Federal Regulations* Title 21 §314 Drug Master Files (DMF). They are as follows:

- Type 1—Reserved (no longer used; once used for facilities).
- Type 2—Drug substances, intermediates, and materials used in their preparation of drug products.
- Type 3—Packaging materials (resins, compounds, colorants, inks, components).
- Type 4—Excipients (colorants, flavors, and raw materials).
- Type 5: FDA-accepted reference information.

Type 1 Drug Master Files are no longer used. They were once used to describe facilities. In an effort to better define the relationship between the field investigators and the center reviewers, the Center/Field Agreement was written, transferring the responsibility for review

of facility information to the field investigator. Facility information on companies that manufacture active ingredients, packaging materials, and raw materials was transferred to the respective Drug Master File.

Type 2 Drug Master Files are required for drug substances, also referred to as active ingredients or active pharmaceutical ingredients. A separate DMF is filed for each active ingredient. The DMF must include a brief description of the facility, the address, a contact, phone number, and fax number. The manufacturing facility must be registered and the number should be listed. A U.S. agent is required to list the active ingredient and register the firm if the site is located outside of the United States. The address should be the same as the address used on the FDA registration form. While a U.S. agent is required for registration, an agent is not required to file a DMF at this time.

Type 2 Drug Master Files should contain a flow diagram of the manufacturing or synthetic process (if it is synthetic) including a list of the critical steps, in-processing tests conducted at those steps, and sampling protocol. The testing of all raw materials should be provided as well as the in-process controls, packaging, release, and stability testing. The impurity profile, particle-size distribution, organic volatile impurities, and residual solvent test results have become increasingly important. These tests should reference the current standards of the United States Pharmacopeia (USP) and the International Conference on Harmonization (ICH) Guidelines. These test results are often compared with those obtained by the end user to validate the results when reviewed by the FDA. If the values are not in agreement, it is a signal that the DMF holder may not be in compliance with the DMF. The testing for polymorphism is increasingly important, and many times is an issue for drug absorption and stability and increasingly in patent litigation. The test methods should be validated if they are not USP. CDER reviewers have standardized the information requirements for Type 2 Drug Master Files through their deficiency letters and guidances.

Guidances for residual solvents, methods validation, changes to the synthetic route, and analytical methods should all be cited in the DMF and used to generate the documentation. As these guidances and test methods evolve, the DMF should be amended to provide for changes and be updated to incorporate changes in USP/NF or FDA standards. The establishment of standards for impurities and residual solvents should not be solely based on the ICH/CDER guidances but should also be established at a low-enough level to demonstrate the control of a process.

Changes in the synthetic route, process, test method, and the loosening of specifications can all have a major impact on the drug application, in which the Drug Master File is referenced. These changes must be classified to

minor or major changes, and a determination must be made as to how these changes are to be reported by the drug company. Changes may require the drug company to manufacture a new test batch with the revised procedure and file a supplement to their approved application before releasing the product to the market. It is in the best interest of the DMF holder to discuss the changes with the end user well in advance of the implementation of the change. Failure to file a change in the DMF, or to notify the end user, can result in regulatory action against the DMF holder. The FDA can also place an embargo on a foreign firm and prevent the import of the active ingredient. The FDA can also "cancel" a DMF if the DMF holder does not follow the requirements stated in the Code of Federal Regulations.

The information submitted in Type 3 DMFs is more variable because the articles can be very different. Most Type 3 DMF holders are ISO (International Organization for Standardization) certified, but the rules for ISO and those of CDER are not always the same. There is an increase in the use of Type 3 Drug Master Files for both contract packaging companies and firms that manufacture either components or parts of components. There is a confusion over what is to be filed in packaging DMFs. A Type 3 DMF can contain information on a number of different packaging components. Typically, separate DMFs are filed for closures, plastic bottles, caps, droppers, stoppers, etc. Each packaging material should be identified by the intended use, components, composition, and controls for its release. The names of the suppliers or fabricators of the components used in preparing the packaging material and the acceptance specifications should also be provided. Data supporting the acceptability of the packaging material for its intended use should also be submitted in conformance with the agency's guidances. Toxicological data can be included where appropriate. Components manufactured at alternate sites can still be filed in the same DMF. For example, bottle manufactured at two different plants in the United States can both be in the same DMF. Blister film manufactured in the United States and overseas can be listed in the same DMF. The addresses for both manufacturing facilities would be provided in the facility section of the DMF.

Manufacturers of resins, colorants, inks, compounds, parts, molded components, container systems, and packaging operations all use Type 3 DMFs. Depending on the subject of the DMF, it should contain the following: A short facility description, the formulation providing the trade name, the generic name, *Code of Federal Regulations* Title 21 indirect food additive reference or Food Contact Number, Chemical Abstract number, and references to other supporting DMFs, if applicable. The DMF should list the quality, quantity, and purpose of each

chemical in the component compound. A brief description of the manufacturing process, drawings (if applicable), and Certificate of Conformance, with critical-to-function or fit testing should also be included. Test methods should be based on public standards such as ASTM (American Society for Testing and Materials) or USP^[3,4] to include physiochemical qualification tests, identity tests, and extractions (USP or other). Firms should specify any additional treatments (such as washing). It is also recommended to include a brief description of packaging and labeling procedures and include samples of labels.

Type 3 DMF holders must be aware of the need to meet additional standards. Certain states and organizations such as the Congress of North East Governors (CONEG), and the states of California and New Jersey have local regulations that must be considered. There are limits for heavy metals, lead, hexavalent chromium, mercury, and cadmium. Mad Cow Certification is required if stearates are used. Testing for Organic Volatile Impurities and residual solvents maybe required. In addition, because most firms ship overseas, international rules may apply as well. Drug Master File holders should follow the FDA regulations and guidances, stay informed, maintain documentation, follow applicable cGMPs, follow DMF practices, and keep customers informed.

The needs of the drug applicant must also be considered. The DMF provide all of the required supporting information on the components that is not contained in the drug submission. Standards and requirements are contained in the USP,^[5] FDA, CDER guidances, and ICH/CDER documents. These documents cover most of the testing needed to assure that the components should not adversely impact the drug and render it unacceptable for use. The lower the drug product risk, the more standard the component and its materials, and the easier it is to provide adequate information and meet drug-applicant needs. Standards for high-density polyethylene bottles for a solid oral dosage form are published in the USP <661> and soon to be revised <671> chapters. Solid oral dosage forms are lower-risk products. The standards are understood and have been in place since the 1970s when the standards in the USP chapters were established. Reviewers and manufacturers are well aware of the resins and the properties requirements for this end use.

Where plastic or elastomeric material is used for high-risk products such as inhalation products, injectable drugs, or implants, the risk is greater and the rules are less clear. The FDA provides guidance in this area, but there is a limit as to what help they can provide prior to reviewing the drug product and component information. The drug applicant is placed in a position of trying to test for extractables from the component without knowing what they are, and the DMF holder is trying to

meet the needs of the customer without compromising their product(s).

The end user does not usually inform the DMF holder as to the product for which the component will be used. It is not unusual for the drug applicant to request a sample supply and a letter of authorization. The DMF holder may be unaware of the status of their DMF. The end user would benefit by telling the DMF holder what the end use of the material or components would be. Through this, the DMF holder can better advise the end user on the choice of components and the degree of testing that they themselves have conducted. The applicant can provide a list of criteria to the DMF holder in advance to be certain the article they purchase meets the product needs. An alternative is to use a confidential third party, to work with both the DMF holder and the drug applicant. With a confidentially agreement signed by both parties, there can be consistency in the information in the DMF. A flow of information from the DMF to the container section of the drug application makes it easier for the FDA to review.

Type 4 Drug Master Files are seldom filed and are not required for raw materials. Most raw materials meet USP/NF standards and need only to meet those criteria for acceptance and certain physical tests. Type 4 DMFs are usually used for flavors and cosmetic coatings for tablets for which USP/NF standards do not exist. Coatings, whether cosmetic or controlled release, may be proprietary in nature. The DMF process allows for these articles to be reviewed, again, under confidentiality. Coatings are usually multiple ingredients. The raw material qualifications, formulation, manufacturing process, and release testing should be provided and iron oxide constituents should be quantitated. It is advisable to include the calculation for iron content for these materials in the DMF.

All DMFs require continuing support. The DMF holder is required to file annual reports and inform the drug applicant of changes to the DMF. The DMF holder must notify each firm authorized to reference the DMF if the DMF holder adds, deletes, or changes information in the DMF. If the holder changes any process or document listed in the DMF, then the DMF must also be changed.

As changes occur, both parties must have a clear understanding of the impact of the change, the method of reporting the change, and the time for the FDA to review the change, if necessary. Changes should be classified based on the cGMPs and the CDER guidances. If the DMF holder is uncertain about the classification of a change or the way in which the drug application should report the changes, it is strongly recommended that the DMF holder contact a regulatory consultant or the agency to discuss the change before it is made. Sufficient information should be provided to the agency in order for the FDA to render a meaningful decision. On the anniversary date of the filing, the holder is to update the

DMF to include changes in the authorization list, manufacturing procedures, designs, suppliers, testing, letters of authorization to other DMFs, and provide a complete updated list of people to whom letters of authorization have been issued. Failure to update these items can result in delays in drug approvals. The FDA agencies can also close the DMF based on failure to provide an annual list of persons authorized to incorporate information, failure to provide a list of changes, and failure to provide a statement that the DMF is current.

Based on its experience or newly provided information, the FDA is constantly updating its practices and issuing revised policies and guidances. It is important for both DMF holders and drug applicants to stay vigilant. Documentation and practices should be reviewed on a routine basis and updated to incorporate changes in the regulations, practices, and guidances.

CONCLUSION

The Drug Master File is a critical document used to support a drug application. Deficiencies in the Drug Master File can result in the delay of approval of drug applications. It is important that the DMF be filed in a timely manner and that the standards used to compete it are of the same quality as the actual drug application. The DMF can be considered an extension of the drug application. The drug review process works best when the required information flows from the DMFs to the drug application.

DRYING AND DRYERS

Anthony J. Hlinak

Bradley A. Clark

Pharmacia, Skokie, Illinois, U.S.A.

INTRODUCTION

Many pharmaceutical operations, including those used to produce active pharmaceutical ingredients and excipients, use water or organic solvents as essential processing aids. However, the continued presence of these processing aids may hamper downstream manufacturing operations or compromise the safety and stability of the final pharmaceutical product. Drying is a common unit operation used to reduce the levels of water or organic solvent in pharmaceutical materials to acceptable levels. Drying requires the use of a manufacturing firm's scarce resources: facilities, equipment, utilities, human labor, and time. Thus, there is often economic pressure to select aggressive drying conditions in an effort to minimize cycle times and increase throughput. However, the drying rate can impact the properties, functionality, and quality of the material being dried. Thus, the practitioner must balance the economic pressure with the quality and performance needs of the product.

In general terms, drying can be described by three processes operating simultaneously. The first process is energy transfer from an external source to the water or organic solvent in the material. The second process is the phase transformation of the water or organic solvent from a liquid or liquid-like state to a vapor state. The third process is the transfer of the vapor generated away from the pharmaceutical material and out of the drying equipment. Analysis of the drying process is complicated by the fact these three processes are coupled to each other, and all three need to be considered simultaneously.

THEORY

Heat Transfer

For most equipment designs, the energy transferred is in the form of heat. Heat flows naturally in the direction of decreasing temperature and is known to transfer by three distinct mechanisms. The first, conduction, involves purely molecular scale transfers of kinetic energy and

can be modeled in one dimension in the steady state using Fourier's equation of heat conduction (1):

$$q_k = -kA \frac{dT}{dx} \quad (1)$$

where q_k is the rate of energy transferred by the conductive mechanism (calories/s), k the thermal conductivity of the transferring medium (calories/s/cm/°C), A the transfer area (cm²), and

$$\frac{dT}{dx}$$

is the temperature gradient in the direction of transfer (°C/cm).

For the simple case of steady one-dimensional heat flow through a homogeneous medium with parallel, planar boundaries held at fixed temperatures, Eq. 1 can be integrated to yield

$$q_k = kA \frac{(T_s - T_i)}{\ell} \quad (2)$$

where T_s, T_i are the exposed surface and interface temperatures, respectively (°C) and ℓ is the thickness of the material layer (cm).

Although derived assuming the simplest of conditions, Eq. 2 can be used to analyze a variety of drying situations as illustrated in Fig. 1, including cases involving modest curvature, as a reasonable approximation. Solutions for more complex cases, including nonplanar geometries, nonsteady state, and complex boundary conditions can be found in classic texts on the subject (2).

A useful concept, known as thermal resistance, can be derived from Eq. 2 by a simple redefinition of terms:

$$q_k = \frac{(T_s - T_i)}{R_k} \quad (3)$$

Here

$$R_k = \frac{\ell}{kA}$$

is the thermal resistance. Eq. 3 takes the functional form of Ohm's law in electrical circuit theory, with

Fig. 1 Application of Eq. 2 to (a) direct heating of a static solids bed, (b) indirect heating of a static solids bed, and (c) fluid bed-drying of a spherical particle.

the temperature difference playing the role of voltage difference, energy flow in the role of current flow, and thermal resistance in the role of electrical resistance. This form emphasizes the importance of the temperature difference as the driving force behind thermal transport and permits the physical factors that make up the thermal resistance to be broken down in detail. Because of this analogy with Ohm's law, thermal "circuits" can be constructed to handle complex cases involving simultaneous transfer with multiple heat transfer mechanisms or sources and the techniques developed for electrical circuits can be used to simplify the analysis.

In the second heat transfer mechanism, convection, molecular scale transfers of kinetic energy are augmented by the macroscopic movement of a fluid transfer medium. Convection is most important as the mechanism of transfer between the solid surface of a static bed or an individual suspended particle and the gaseous medium that surrounds it. Convection has been modeled classically using the following relationship generally attributed to Isaac Newton:

$$q_c = \bar{h}_c A (T_\infty - T_s) \quad (4)$$

where q_c is the rate of energy transferred attributable to convection (calories/s), T_s the exposed solid surface temperature ($^{\circ}\text{C}$), T_∞ the fluid temperature far away from the exposed solid surface ($^{\circ}\text{C}$), A the transfer area (cm^2), and \bar{h}_c is the average convective heat transfer coefficient (calories/s cm^2 $^{\circ}\text{C}$).

The apparent simplicity of Eq. 4 can be misleading, because the convective heat transfer coefficient is actually a very complex function of fluid flow conditions, fluid properties, and system geometry. In addition, the fluid flow patterns are significantly different depending on whether or not the fluid motion is induced by buoyancy forces alone (termed natural or free convection), or generated by external mechanical means using pumps or blowers (termed forced convection). When a heated fluid passes over a solid surface, the regions of significant velocity and temperature change are generally restricted to a small layer in the immediate vicinity of the solid surface. This boundary layer may consist entirely of fluid moving in the

laminar flow regime, where transport of both momentum and energy rely solely on molecular interactions. More generally, the boundary layer consists of both a laminar sublayer immediately adjacent to the solid surface and a turbulent region.

Classical techniques have relied heavily on dimensional analysis (3), the combining of the many variables into physically meaningful nondimensional groups, supported with experiments to quantify heat transfer for various geometries. For most drying applications of pharmaceutical relevance, the most important of these nondimensional groups are the Nusselt number (\overline{Nu}), the Prandtl number (Pr) and the Reynolds number (Re), defined as follows:

$$\overline{Nu} = \frac{hL}{k_f} \quad (5a)$$

$$Pr = \frac{c_p \mu}{k_f} \quad (5b)$$

$$Re = \frac{VL\rho}{\mu} \quad (5c)$$

Here, k_f , c_p , ρ , and μ are, respectively, the thermal conductivity, specific heat at constant pressure, density, and dynamic viscosity of the convective fluid; V is the relative velocity between fluid and solid; and L is a geometry dependent, characteristic length dimension for the system. Note that the Pr is composed exclusively of fluid properties and that the Re will increase in direct proportion to the relative velocity between fluid and solid surface. Example applications are shown in Fig. 2.

Knowledge of \overline{Nu} , fluid phase thermal conductivity, and characteristic length allows computation of the average convective heat transfer coefficient, using Eq. 5a. For flat surfaces, like the surfaces of static beds exposed to air or other gases ($Pr \approx 0.7$), Kreith (4) provides the following for low-velocity, laminar flow conditions

$$\begin{aligned} \overline{Nu} &= 0.664 Re_L^{0.5} Pr^{0.33} \\ \text{for } Pr &> 0.1 \\ \text{and } Re_L &< 5 \times 10^5 \end{aligned} \quad (6a)$$

and for high-velocity, turbulent conditions

$$\begin{aligned} \overline{Nu} &= 0.036 Pr^{0.33} [Re_L^{0.8} - 23, 200] \\ \text{for } Pr &> 0.5 \\ \text{and } Re_L &> 5 \times 10^5 \end{aligned} \quad (6b)$$

Fig. 2 Convective heat transfer applications in pharmaceutical drying: (a) tray-drying of a static solids bed; and (b) fluid bed-drying of a spherical particle.

For a spherical particle moving in an air or other gaseous stream, Whitaker (5) recommends the following relationship:

$$\overline{Nu} = 2 + (0.4 Re_L^{0.5} + 0.06 Re_L^{0.67}) Pr^{0.4} (\mu_s / \mu_\infty)^{0.25} \quad (6c)$$

for $3.5 < Re_L < 76,000$

where μ_s and μ_∞ are the dynamic viscosities of the gas at the temperature of the particle surface and at the temperature far away from the surface, respectively. In the limiting case of $Re_L \ll 1$, Johnston et al. (6) have shown that the \overline{Nu} approaches the constant value of 2, using assumptions approximating spherical particles in gas streams.

Equipment designs based on indirect conduction usually transfer the heat from the primary heat transfer fluid to the intermediate wall within some kind of internal duct or channel. Transfer coefficients for these cases depend on the nature of the flow (laminar or turbulent) and the geometry of the duct or channel (short or long). Expressions for evaluating the transfer coefficients for these cases are available in standard texts (7).

An expression for the convective thermal resistance can be generated similar to that derived for the conductive resistance:

$$q_c = \frac{(T_\infty - T_s)}{R_c} \quad (7)$$

Here, $R_c = \frac{1}{h_c A}$, is the convective thermal resistance.

The third mechanism of heat transfer is thermal radiation that can be defined as radiant energy emitted by a medium by virtue of its temperature. The wavelengths of thermal radiation produced by emitting bodies fall roughly between 0.1 and 100 μm , which includes portions of the ultraviolet, visible, and infrared spectra. The net exchange of radiant thermal energy between two surfaces can be characterized by the following relationship

$$q_r = \sigma A_1 \mathfrak{J}_{1-2} (T_1^4 - T_2^4) \quad (8)$$

where q_r is the rate of energy transferred attributable to thermal radiation (calories/s), T_1 the absolute temperature of radiating surface 1 (K), T_2 the absolute temperature of radiating surface 2 (K), σ the Stefan-Boltzmann constant (1.35×10^{-12} cal/s $\text{cm}^2 \text{K}^4$), A_1 the transfer area of surface 1 (cm^2), and \mathfrak{J}_{1-2} is a dimensionless factor that corrects for the radiative properties and relative geometries of the surfaces involved in the exchange.

Most of the complexity of radiative heat transfer analysis is thus condensed into evaluation of the dimensionless factor \mathfrak{J}_{1-2} . This factor is a function of both surface properties and the geometric orientation of the surfaces involved in the exchange. For real surfaces the amount of thermal radiation emitted and absorbed depends on the temperature, the wavelength, and the angular direction. These complications are often neglected and the radiative properties of the surface are lumped together into a dimensionless factor that is independent of both wavelength and direction, referred to as emissivity (ϵ). The emissivity expresses the radiative power of a surface as some fraction of an ideal radiator or blackbody. Real surfaces so treated are referred to as greybodies to emphasize this simplification imposed. For exchanges between parallel rectangular surfaces, where the spacing between the surfaces is small compared with the smaller dimension of the rectangles, the factor \mathfrak{J}_{1-2} can be estimated as

$$\mathfrak{J}_{1-2} = \frac{1}{\frac{1}{\epsilon_1} + \frac{1}{\epsilon_2} - 1} \quad (9)$$

where, ϵ_1 , ϵ_2 are the emissivities of the surfaces involved in the exchange. For a small spherical particle inside a large enclosure, the factor \mathfrak{J}_{1-2} can be estimated as

$$\mathfrak{J}_{1-2} = \epsilon_1 \quad (10)$$

where ϵ_1 is the emissivity of the spherical particle. For more rigorous treatments, the reader is advised to consult advanced texts (8). Eq. 8 can be used to generate an expression for the thermal radiative resistance similar to that derived for the conductive and convective resistance:

$$q_r = \frac{(T_\infty - T_s)}{R_r} \quad (11)$$

Here the thermal radiative resistance must assume a more complex form

$$R_r = \frac{(T_\infty - T_s)}{\sigma A_s \mathfrak{J}_{s-2} (T_s^4 - T_2^4)} \quad (12)$$

with the subscripts s and 2 used to denote the product surface and external radiating surface, respectively.

Unfortunately, the resistance defined by Eq. 12 cannot be evaluated without a priori knowledge of temperatures, unlike those defined previously for conduction and convection. However, enough information on temperatures is often available from previous drying experience to permit useful estimates of the radiative resistance to be established.

Application of the Ohm's law analogy allows construction of combined series parallel thermal circuits to describe a specific drying application. The flow of heat energy through the circuit shown in Fig. 3 can be described as

$$q = \frac{(T_\infty - T_i)}{R_T} \quad (13)$$

where

$$R_T = R_k + \frac{R_c R_r}{(R_c + R_r)} \quad (14)$$

is the total resistance to heat transfer for the circuit. If $R_r \gg R_c$ then the radiation transfer mode can be neglected and the total resistance simplifies to

$$R_T = R_k + R_c \quad (15)$$

In the early stages of the drying operation, the thermal resistance attributable to conduction through the dried layer will be negligibly small for the cases illustrated in Figs. 1a and c because the thickness ℓ will approximate zero. For this early stage, the thermal resistance would be

$$R_T = \frac{R_c R_r}{(R_c + R_r)} \quad (16)$$

Fig. 3 Construction of a thermal circuit for a drying application.

or

$$R_T = R_c \quad (17)$$

depending on whether or not thermal radiation is appreciable. For a fixed temperature difference and flow rate, we would then expect to generate a constant heat transfer rate during this initial drying period, since the parameters that make up R_T using either Eq. 16 or Eq. 17 are at most dependent on fluid velocity and temperature. As drying proceeds we will expect the thermal resistance attributable to conduction through the growing dried layer to increase and eventually become a significant part of the total resistance. If temperature and flow conditions are fixed, we would therefore expect a decrease in heat transfer rate with time. Heat will continue to flow as long as there is a temperature difference between the energy source and the product.

Mass Transfer

The vapor generated during drying must migrate from the liquid vapor interface through the dried material layer and then be transported out of the drying equipment. For purely diffusional transport, exact solutions to Fick's law are available for a variety of geometric configurations and boundary conditions, usually in the form of infinite series. For a layer of wet material drying off the top surface from an initial uniform concentration of c_0 with the top surface maintained at a constant concentration of c_1 the drying rate for a purely diffusion based transfer mechanism is (9)

$$\dot{m} = \frac{2D(c_0 - c_1)}{\ell} \sum_{n=0}^{\infty} \exp \left[\frac{-(2n+1)^2 \pi^2 D t}{4\ell^2} \right] \quad (18)$$

where \dot{m} is the rate of vapor transferred by the diffusion mechanism (g/s), D the mass diffusivity of the dried layer (cm^2/s), A the transfer area, (cm^2) ℓ the layer thickness (cm), and t the elapsed time (s).

Eq. 18 leads to the following expression for the expected drying curve

$$\frac{M(t)}{M_0} = \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp \left[\frac{-(2n+1)^2 \pi^2 D t}{4\ell^2} \right] \quad (19)$$

where $M(t)$ is the amount of solvent in the dried material at time t (g), and M_0 is the initial amount of removable solvent (g).

The corresponding expressions for the drying rate and drying curve of a spherical particle from an initial uniform concentration of c_0 with the exposed surface maintained at a constant concentration of c_1 are (10)

$$\dot{m} = 8Dr_0\pi(c_0 - c_1) \sum_{n=1}^{\infty} \exp\left[\frac{-n^2\pi^2Dt}{r_0^2}\right] \quad (20)$$

and

$$\frac{M(t)}{M_0} = \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp\left[\frac{-n^2\pi^2Dt}{r_0^2}\right]. \quad (21)$$

where r_0 is the particle radius. Expressions such as Eqs. 18 and 20 illustrate the role of concentration difference as the driving force behind mass transfer and predict a decrease in drying rate with time. However, these expressions tend to overstate the magnitude of the decrease and the dependence on layer thickness and/or particle radius (11).

The total mass transferred will include the combined effect from a number of mechanisms, including molecular diffusion through the solid via vacancies and interstitial defects, migration along dislocations, grain boundaries, and along surfaces of internal pores and fissures, and molecular diffusion through the vapor filled passages defined by the internal pores and fissures (12, 13). In cases where the total pressure inside the material is higher than ambient, the transport mechanism could include convective flow through the pores and fissures.

The two-zone model described above allows for the multiple mechanisms. The rules that govern these mass transfer operations are completely analogous to those governing heat transfer already discussed. The migration of vapor through the dried material layer can be expressed as

$$\dot{m} = -D_{\text{eff}}A \frac{dc}{dx} \quad (22)$$

where $\frac{dc}{dx}$ is the concentration gradient in the direction of transfer ($\text{g/cm}^3/\text{cm}$). The effective mass diffusivity (D_{eff}) will include the combined effect from all the mechanisms outlined above.

Eq. 22 can be recast using vapor phase pressure as the driving force behind the mass transfer, using the ideal gas relationship,

$$\dot{m} = -D_{\text{eff}}A \left(\frac{MW_s}{RT}\right) \frac{dp}{dx} \quad (23)$$

where MW_s is the molecular weight of the solvent (g/mole), R the molar gas constant ($62364.1 \text{ mm Hg cm}^3/\text{mole K}$) and T is the absolute temperature ($^{\circ}\text{K}$).

Using appropriate simplifying assumptions, Eq. 23 can be integrated and placed in a form analogous to Eq. 3

$$\dot{m} = \frac{(p_s - p_i)}{R_D} \quad (24)$$

where p_s, p_i are the vapor pressures at the exposed surface and interface, respectively (mm Hg), and

$$R_D = \frac{\ell}{D_{\text{eff}}A} \left(\frac{RT}{MW_s}\right) \left(\frac{p_m}{P}\right) \quad (25)$$

is the effective mass transfer resistance of the dried layer (mm Hg s/g). Here P is the total pressure and

$$p_m = \frac{(p_s - p_i)}{\ln\left(\frac{P - p_i}{P - p_s}\right)} \quad (26)$$

referred to as the logarithmic mean partial pressure, accounts for the fact that the partial pressures of the individual components in a multicomponent system must equal the system's total pressure. For dilute mixtures of solvent vapor in air, $p_m \cong P$ and the pressure ratio on the right-hand side of Eq. 25 approximates 1.

Solvent transfer from the surface of the dried material can be treated in a manner analogous to Eq. 4 above for heat transfer. An expression for the convective mass resistance can be generated similar to that derived for the thermal resistance:

$$\dot{m} = \frac{(p_{\infty} - p_s)}{R_c} \quad (27)$$

Here, $R_c = \frac{1}{\bar{h}_G A}$, is the convective mass resistance (mm Hg s/g), \dot{m} is the rate of vapor transferred from the exposed surface (g/sec), p_s is the partial pressure of solvent at the exposed solid surface temperature (mm Hg), p_{∞} is the partial pressure of solvent far away from the exposed solid surface (mm Hg), A is the transfer area (cm^2), and \bar{h}_G is the average convective mass transfer coefficient ($\text{g/s-cm}^2\text{-mm Hg}$).

Convective mass transfer coefficients must generally be determined by experiment. Again dimensional analysis can be used to determine physically meaningful nondimensional groups to guide experimental designs. For most drying applications of pharmaceutical relevance, the most important of these nondimensional groups are the Sherwood number (Sh), the Schmidt number (Sc), and the Reynolds number (Re). The Sh and Sc are defined as follows:

$$Sh = \frac{\bar{h}_G L}{D_v} \left(\frac{RT}{MW_s}\right) \left(\frac{p_m}{P}\right) \quad (28a)$$

$$Sc = \frac{\mu}{D_v \rho} \quad (28b)$$

Here, D_v is the mass diffusivity of the solvent through the convective fluid and all other parameters are as defined previously.

The powerful analogy that exists among momentum, heat, and mass transport permits useful values of convective mass transfer coefficients to be calculated from known values of convective heat transfer coefficients. For a particular drying system with a specific geometry and flow characteristics, the following relationship is recommended (14).

$$\bar{h}_G = \left(\frac{\bar{h}_c}{c_p \rho} \right) \left(\frac{MW_s}{RT} \right) \left(\frac{P}{p_m} \right) \left(\frac{Pr}{Sc} \right)^{0.67} \quad (29)$$

Once again, application of the Ohm's law analogy allows construction of mass transfer circuits to describe a specific drying application. The mass flow through the circuits derived from Fig. 2 can be described using

$$\dot{m} = \frac{(p_i - p_\infty)}{R_T} \quad (30)$$

where

$$R_T = R_D + R_c \quad (31)$$

The mass transfer resistance of the dried layer will be negligibly small for some period at the start of drying because the dried layer thickness, starts at zero. During this period the total resistance to mass transfer will equal the convective resistance. For fixed flow, temperature, and solvent concentration far from the exposed product surfaces, the drying rate will be constant during this period. As drying proceeds the resistance of the dried layer becomes a significant portion of the total resistance and continues to increase with time. The drying rate would steadily decrease during this period even if the solvent pressure difference could be held constant.

Phase Transition

The liquid solvent added to a pharmaceutical material generally exists in a variety of states (15). Some will condense or be pulled by capillary forces into macroscopic pores and fissures or into the interstitial spaces between particles. A state of local equilibrium can be assumed to exist at the interface between the liquid and vapor phases of solvent so situated. As a result, the temperature and vapor pressure exerted by the condensed solvent will not be independent of one another. Fig. 4 shows the equilibrium vapor pressure versus temperature relationship for a number of common solvents (16). Heats of vaporization are shown parenthetically (17). Among common solvents, acetone has the highest vapor pressure and water the lowest. Water requires three–five times the energy of the common organic solvents to vaporize.

Fig. 4 Vapor pressure curves for common solvents. Heats of vaporization are shown parenthetically. (From Refs. 16 and 17.)

Some of the solvent added will adsorb to the solid surfaces of crystalline solids, particularly at higher energy sites resulting from surface defects and impurities. The amount adsorbed will increase in proportion to the exposed surface area and as the partial pressure of solvent vapor above the surface increases. Solvent can also concentrate in the crystal interior by migrating along high-diffusion paths produced by dislocations and grain boundaries (18). Some polymeric materials of pharmaceutical interest, such as starches and celluloses, often exhibit noncrystalline or amorphous structures. Such materials will typically take up solvent in significantly greater quantities than do crystalline materials with the amount absorbed independent of surface area. As with crystalline solids the amount sorbed will increase as the partial pressure of solvent vapor in contact with the material increases. Sorption data can be experimentally generated and fitted to a variety of available models, including the well-known BET equation, and the more generally applicable 3-state extension developed by deBoer and Guggenheim (19). Data on a number of relevant pharmaceutical materials have been compiled by Callahan and collaborators (20).

In some cases the water or organic solvent added move to regular positions in the crystal lattice and form a stoichiometric relationship with the original molecules resulting in a hydrate or solvate crystalline structure that differs from that of the original crystalline material. Solid state techniques, such as X-ray diffraction, can be used to detect these structural changes. For these materials the impact of solvent addition and removal through drying must be carefully considered as new states with unknown or undesirable properties could be inadvertently generated. In the case of erythromycin, researchers have reported that the method of removing the water of hydration leads to a collapse of the crystalline structure into a metastable amorphous form (21). On the other hand, Schilling and coworkers monitored the formation of a hydrated form of a

5-lipoxaginase inhibitor during wet granulation and subsequent return to the desired anhydrous state after fluid bed-drying (22).

The energy that flows to the water or organic solvent interface is used in two ways. First, and most desirable, it is used to transform the water or organic solvent from a liquid or liquid-like state to a vapor state. The second use, often less desirable, is to raise the temperature of the interface. The distribution can be expressed in terms of an energy balance

$$q_t = \dot{m}\Delta h + Mc_p \frac{(T'_i - T_i)}{\Delta t} \quad (32)$$

where q_t is the total rate of energy transferred to the interface from all sources and mechanisms (calories/s), Δt the time interval under consideration (s), T'_i the temperature of the interface at the end of the time interval ($^{\circ}\text{C}$), T_i the temperature of the interface at the beginning of the time interval ($^{\circ}\text{C}$), Δh the solvent's heat of vaporization (calories/g), M the effective mass of wet product associated with the interface (g), c_p the heat capacity of the wet product (calories/g $^{\circ}\text{C}$), and \dot{m} is the drying rate (g/s).

Eq. 32 can be used to understand the link between drying rate, heat flow, and temperature rise during drying. If the resistance to mass transfer is sufficiently low so solvent vapor molecules generated at the interface can freely escape from the solid, then the bulk of the energy supplied will be absorbed by the first term on the right-hand side of Eq. 32 and the interface will remain cool. This is generally the case near the beginning of the drying cycle because the mass transfer barrier created by a dried product layer has not yet formed. The rate of energy transferred is generally fixed by inlet temperature and flow conditions, leading to a constant drying rate. This portion of the drying cycle is referred to as the constant rate period. As the dried product layer builds the vapor molecules generated cannot readily escape, causing the vapor pressure at the interface to increase. Because temperature and pressure at the interface are related through the equilibrium relationship, the interface temperature increases as the vapor pressure increases. More and more of the energy supplied then shifts from the first to the second term on the right-hand side of Eq. 32 resulting in a drop in the drying rate and a product temperature rise during the time interval. This portion of the drying cycle is referred to as the falling rate period. The higher interface temperature and higher heat transfer resistance created by the dried product barrier serve to reduce the rate of energy transfer in subsequent time intervals as predicted by Eq. 13. The higher interface pressure partially offsets the effect of increasing the mass transfer resistance.

Psychrometrics

The solvent vapor generated during drying must be transported out of the drying equipment. If it isn't, the gas surrounding the material to be dried will soon become saturated with vapor and drying will cease. Various interconvertible terms have evolved over time to express the amount of solvent that is absorbed by the drying gas. Many of the common terms have been defined strictly to apply to the air-water vapor system. However, the concepts involved apply equally well to any solvent-drying gas combination. The most common term is that of relative humidity (ϕ), which expresses the ratio of the actual amount of water vapor present to the maximum amount that could be present at a specified temperature. Amounts can be expressed in any consistent way, including units of mass, moles, or partial pressures. For drying applications, partial pressures are particularly convenient and the relative humidity becomes

$$\phi = \frac{p_{\infty}}{p_{\text{sat}}} \quad (33)$$

where p_{∞} is the partial pressure of solvent vapor present and p_{sat} is the maximum pressure at saturation. The saturation pressures for common solvents have been shown previously (Fig. 4) as a function of temperature. For ease of computation, saturation data can be fit to an equation of the form

$$\ln(p_{\text{sat}}) = A + \frac{B}{T} + C \ln(T) + DT \quad (34)$$

where T is the absolute temperature and the constants A , B , C , and D depend on the solvent (23). Recommended constants for the common solvents, determined through regression, are listed in Table 1 for p_{sat} in mm Hg and temperature expressed in K.

An alternate expression for solvent content is the specific humidity or humidity ratio, which is defined as the ratio of the mass of solvent vapor present to the mass of dry gas

$$\omega = \frac{m_v}{m_g} = \left(\frac{\text{MW}_v}{\text{MW}_g} \right) \left(\frac{P_v}{P_g} \right) \quad (35)$$

Eqs. 33, 34, 35 allow interconversion from one expression for solvent content to another. For example, knowledge of temperature, total pressure, and relative humidity allows the humidity ratio to be determined using

$$\omega = \left(\frac{\text{MW}_v}{\text{MW}_g} \right) \left(\frac{\phi P_{\text{sat}}}{P - \phi P_{\text{sat}}} \right) \quad (36)$$

Solvent content can be portrayed graphically in what is known as a psychrometric chart, such as the one for an air

Table 1 Recommended constants for computing saturation pressure, using Eq. 34 for common solvents (p_{sat} in mm Hg and T in K)

Solvent	A	B	C	D
Water	70.708779	-7175.9470	-7.9064596	0.0053125111
Ethanol	-93.710636	-2458.5969	20.649371	-0.039031369
Isopropyl alcohol	-7.4598754	-5.017.1464	5.7374144	-0.015489516
Acetone	92.141422	-6280.1292	-12.241911	0.013701258

water system at atmospheric pressure shown in Fig. 5. Such a chart is a convenient tool for converting between the different expressions for solvent content and for tracking changes in solvent content during drying. Say, for example, that drying air enters a dryer at 60°C and a relative humidity of 0.05 (point A in Fig. 5) and leaves at 30°C and a relative humidity of 0.90 (point B in Fig. 5). Moving horizontally and to the left from point A shows the inlet condition corresponds to a moisture vapor pressure of approximately 7.5 mm Hg and by moving horizontally and to the right shows a humidity ratio of approximately 0.006. The exit condition (point B in Fig. 5) corresponds to a humidity ratio of 0.024 for a difference of approximately 0.018 g of water vapor carried out of the system per gram of dry air. The intersection of the moisture content (horizontal) lines with the saturation curve ($\phi = 1.0$) uniquely defines the so called dew point temperature, indicated in Fig. 5, which is yet another way of specifying solvent content. Fig. 5 can also be used to illustrate the effect of product temperature on the mass transfer driving force. For example, product at 17.5°C (point C in Fig. 5) would provide a driving force of approximately 7.5 mm Hg (15.0–7.5 mm Hg) between the solvent vapor interface and the inlet drying air. A modest temperature rise to 24°C approximately doubles the driving force with the same inlet air by increasing the vapor pressure at the solvent vapor interface.

**Fig. 5** Psychrometric chart for an air–water system at a total pressure of 760 mm Hg.

PRACTICE

Drying can be carried out successfully using a variety of commercially available equipment designs. Pharmaceutical drying equipment has been classified according to principal mode of operation in a recently published regulatory guidance document (24) as shown in Table 2. Equipment classified as direct heating allows intimate contact between the material being dried and the heat energy source, usually a heated gas. That same gas is used to transport the vapor generated from the equipment. In indirect conduction, the energy is transferred from the source, usually a heated liquid, to the material being dried through a conducting wall. In this case other means must be used to remove the generated vapor from the equipment. Radiant approaches do not rely on temperature to generate or transfer the needed energy to the material being dried. Instead, the material is exposed to electromagnetic energy at frequencies strongly absorbed by the solvent being targeted for removal. Specialized approaches, such as spray drying and lyophilization, are treated in separate articles in this encyclopedia and will not be covered more here.

Tray and Truck-Drying

Historically, the most common method of drying of pharmaceutical powders has been tray-drying. With this method, wet powder or granulation is placed on paper-lined trays, usually solid or perforated metal, which are then placed directly onto racks in a drying chamber (oven) or onto movable racks, or trucks, that are wheeled into an oven. The heat and low relative vapor pressure of solvent provided by the flow of heated, dry air throughout the chamber provide a driving force for solvent transfer to and subsequent removal from the particle surfaces of the powder. This results in the gradual overall loss of solvent from the bulk powder.

The drying process from solids has been characterized by three drying regions, as shown in Fig. 6 (12, 25). The

Table 2 Classification of pharmaceutical drying equipment

Class	Subclass	Common names
Direct heating	Static solids bed	Tray and truck dryers
	Moving solids bed	Belt dryer
	Fluidized solids bed	Fluid bed dryer
	Dilute solids bed	Spray dryer
Indirect conduction	Moving solids bed	Tumble dryer
	Gas stripping	Zanchetta
	Static solids bed	Heated shelf tray drier
	Lyophilizers	Freeze dryer
Radiant	Microwave, moving solids bed	Microwave dryer

first, termed the Constant Rate Period, is the initial drying phase in which surface moisture exceeds a critical level and rate is controlled by surface area. When the level of moisture falls below the critical level, it begins to be controlled by mass transfer from inside the solid mass: this is called the First Falling Rate Period. As drying proceeds, mass transfer is not able to supply moisture to the surface of the solid mass at a rate equal to the drying rate, and the free water content at the surface goes to zero. At this time, the surface temperature rises rapidly, and a receding evaporation front may be formed that divides the solid into a wet region and a dry or sorption region. This is the beginning of the Second Falling Rate Period, during which mass transfer of moisture vapor through the sorption region becomes more and more retarded.

The falling rate portion of the drying process can be generally modeled by using a variation of Eq. 19 in which the summation is truncated after one term:

$$\ln\left(\frac{M(t)}{M_0}\right) = -\left(\frac{\pi^2 D}{4\ell^2}\right)t + \ln\left(\frac{8}{\pi^2}\right) \quad (37)$$

**Fig. 6** The phases of the drying process. (From Ref. 12.)

Eq. 37 can be simplified to

$$\ln\left(\frac{M(t)}{M_0}\right) = -kt - 0.2 \quad (38)$$

where k is a first-order drying rate constant such that when $\ln(M(t)/M_0)$ is plotted versus time a straight-line relationship is obtained with a slope of $-k$ (11). This becomes very useful in trying to model the tray-drying process and evaluating the impact of process variables such as bed thickness and drying temperature changes. An example of this is given in Fig. 7, in which drying rate constants obtained at multiple temperatures are plotted versus inverse temperature, allowing one to predict drying rate at any interpolated temperature.

During the drying process, internal liquid transport occurs via capillary flow, while vapor transport occurs both via diffusion and true mass flow driven by pressure gradients (12, 26). Because the powder bed is static,

**Fig. 7** Temperature dependence of drying rate constant (k from Eq. 38). (From Ref. 11.)

significant resistance to the diffusion of solvent from the bed as a whole reduces the rate of drying, thereby limiting the efficiency of this method of drying. This is demonstrated by the dependence of the first order rate constant k on the depth of the bed being dried. Theoretically it is shown that the drying rate constant is an inverse function of the square of the bed thickness (see Eq. 37), but experimental data shows a relationship that more closely resembles an inverse relationship of k with the first order of bed depth (11).

Tray-drying is also used as a method to remove water from soft elastic gelatin capsules (27), and can be model according to Eq. 39a:

$$\ln(c - c_\infty) = -\frac{t}{\Gamma} + \ln(c_0 - c_\infty) \quad (39a)$$

where

$$\Gamma = \frac{h^2}{5.8D} \quad (39b)$$

Here c is the amount of moisture at time t , c_0 , c_∞ the amounts of moisture at time zero and infinity, respectively, h the thickness of the gelatin film, and D is the diffusion coefficient of moisture through gelatin.

This modeling becomes important as a soft-gel product is being developed and a drying end point needs to be established and reproduced.

Despite the low relative capital investment required for tray-drying, it provides a low rate of drying and the loading and unloading of trays is a labor-intensive process. Although still commonly found in both drug substance and drug product manufacturing procedures, tray-drying has become less popular in comparison to other more efficient, reproducible, and well-defined drying procedures such as fluid bed and vacuum tumble drying.

Fluid Bed Dryers

Fluid bed-drying is a widely used example of the direct heating classification. Drying is accomplished by suspending the particles to be dried directly in a stream of heated air or other gaseous media. The intimate contact and high surface areas available for transfer result in fast, efficient drying, often making fluid bed the approach of choice for high-volume products.

A typical installation is shown in Fig. 8. Ambient air enters an air-handling unit through a coarse filter in the lower right. The air is first passed over a chilled, condensing coil to reduce the moisture content. The air leaving the coils can be assumed to be in equilibrium with the condensed water so the temperature measured at the

Fig. 8 Schematic of a typical fluid bed dryer installation.

coil outlet represents the wet bulb temperature, a measure of moisture content. The coolant temperature determines the degree of dehumidification achieved. Chilled water and refrigerant are common coolants. A portion of the inlet air is then diverted through louvers past a heat source and then allowed to remix with the portion not diverted. A steam coil is commonly used as the heat source. The louvers are mechanically linked so that one flow path opens as the other closes. A feedback loop can be established between the downstream temperature and the louver position to control drying temperature. If the drying temperature drops below the set point, the louver position is adjusted to divert a larger fraction of the incoming airflow past the heat source, resulting in a higher temperature of the remixed streams. If the drying temperature drifts above the set point, the louvers are repositioned to divert less past the heat source. This type of arrangement is referred to as *face and bypass control* and has the advantage of fast response time and minimal overshoot. The warm, dehumidified air is then passed through a second, finer filter and sent to the dryer.

The product to be dried is placed inside a bowl on top of a retaining screen. The retaining screen can be of the wire mesh, perforated plate, gill plate, or combination design. As the drying air enters the bowl from below, it drags the product particles off the retaining screen and entrains them in the flow stream. The air transfers heat energy to the suspended particles and collects the solvent vapors given off. A small part of the heat energy supplied to the drying air stream is lost through transfer to the surrounding environment. Product filters are provided to prevent the entrained particles from leaving the drying chamber. A split filter design allows for periodic cleaning without disrupting the drying operation. Flow through one filter

segment can be interrupted so it can be mechanically shaken or reverse-pulsed with clean air to remove accumulated particles. Flow then resumes and the cleaning operation is performed on the other segment.

Drying air flow rate control is achieved using a blower that works against a flow control valve. Both are typically located on the downstream side of the drier to maintain the drying chamber at a slight but not excessive negative pressure with respect to ambient. Product particles and organic solvent vapors are thus unable to escape against the negative pressure gradient. The airflow rate is measured, usually on the clean and dry upstream side of the drier, and a feedback loop is established with the flow control valve. Flow control is achieved by adjusting the position of the flow control valve. Before releasing the used air back into the environment, it is filtered once more to remove any pharmacologically active and potentially hazardous product particles that may have leaked past the product filters. For organic vapor applications, the spent air would also be treated to separate and remove the vapors from the air stream before releasing it back to the environment. Grounding, containment, and venting strategies are incorporated into the designs to control explosion hazards.

The dryer bowl is designed in the shape of an inverted frustum of a right circular cone, with the smaller diameter at the bottom of the bowl. As the drying air passes up through the bowl, the increasing area causes the flow velocity to drop in the direction of flow. At the lower velocity the larger, heavier particles can no longer be sustained and they fall back toward the retaining screen. The situation represents a tension between the drag forces exerted on the particle by the moving fluid and the force of gravity trying to pull the particle back down to the retaining screen. For spherical particles moving at low velocity in a fluid stream the expression for the drag force first determined by Stokes (28) can be set equal to the particle weight to yield an expression for the minimum fluidization velocity (29)

$$V = \frac{gd^2}{18\mu}(\rho_p - \rho) \quad (40)$$

where V is the minimum fluidization velocity (cm/s), d the particle diameter (cm), g the acceleration of gravity (980 cm/s²), ρ_p the particle density (g/cm³), and ρ and μ are the density and dynamic viscosity of the fluid, respectively.

Strictly speaking, Eq. 40 is a good approximation only at low Re , that is at particle diameters significantly less than 0.01 cm (100 micrometers). White (30) has provided a formula extending the range to particle diameters as high as 1 cm, using a curve fit of data from many sources. A plot

Fig. 9 Fluidization velocity as a function of diameter and density for spherical particles suspended in an air stream at 45°C, using the curve fit of White. (From Ref. 30.)

of fluidization velocity as a function of particle diameter (in microns) and density is shown in Fig. 9 assuming spherical particles in air at 45°C, using White's formula. Typical commercial equipment provides velocities in the range of 150–250 cm/s at the retaining screen that drop after expansion into the range of 60–100 cm/s. Because particle density drops as drying proceeds, flow rates used at the beginning of drying to fluidize the particle bed could be reduced later in the cycle without losing entrainment.

The drying rate at any point in the drying cycle can be derived from information provided from available process instrumentation without resorting to intrusive sampling during the process. An energy balance across a control volume surrounding the drying bed yields:

$$\dot{m} = \frac{\dot{m}_g C_{p,g}(T_{in} - T_{out}) - Q_{loss}}{h_{fg}} \quad (41)$$

where \dot{m} is the drying rate, $C_{p,g}$ the specific heat capacity of drying gas at constant pressure, \dot{m}_g the mass flow of drying gas through dryer, T_{in} the inlet temperature of dryer gas, T_{out} the outlet temperature of dryer gas, Q_{loss} the heat loss to the environment through thermal convection, and h_{fg} is the latent heat of vaporization for solvent.

The heat loss term can be estimated by applying Eq. 41 to conditions near the end of the drying cycle, where the evaporation rate is negligible.

$$Q_{loss} = [\dot{m}_g C_{p,g}(T_{in} - T_{out})]_{\text{end of cycle}} \quad (42)$$

Using these conditions, the $\bar{h}A$ term is then calculated from the following equation and is assumed constant throughout the drying cycle:

$$Q_{loss} = \bar{h}A(\bar{T} - T_{amb}) \quad (43)$$

where \bar{h} is the average convective heat transfer coefficient, A the external dryer surface available for heat transfer, \bar{T}

Fig. 10 Temperature and drying rate histories for a water-based drying case in air (a) temperature history; (b) computed drying rate history. (From Ref. 31.)

the average temperature in the drying bed, and T_{amb} is the ambient temperature.

The temperature and computed drying rate histories for a water based drying case in air at a constant flow rate of $2.36 \times 10^6 \text{ cm}^3/\text{s}$ (5000 ft^3/min) is shown in Fig. 10 (31). The heat loss term parameter $\bar{h}A$ is computed to be 17.9 $\text{cal/s}/^\circ\text{C}$ for this case. An early constant rate period is evident that extends out to the first 30 min of drying in which a drying rate of approximately 40 g/s is achieved.

Because different mechanisms limit the drying rate in each of the drying periods, scheduled changes in flow rate and inlet temperature have been used with great success to shorten drying cycles without subjecting the pharmaceutical material to unnecessary stress (31, 32). During the constant rate period, the drying rate is limited by the enthalpy available in the inlet air and its capacity to absorb the vapor that is generated. Increases in flow rate and inlet temperature can be used to reduce the length of the constant rate period. Staged reductions in inlet temperature and flow rate can be scheduled without impacting the rate during the falling rate and equilibration periods because internal moisture transfer limits the overall rate. The lowest flow rates can be used during the equilibration

period because the low-moisture, low-density particles are easiest to fluidize and because dehumidification techniques should become more efficient, resulting in inlet air with lower moisture content.

Vacuum Drying

Vacuum can be used with all of the indirect conduction and microwave approaches to drying. The total pressure surrounding the pharmaceutical material is reduced to levels below the saturation pressure of the solvent at the interface between the wet and dry layers causing generation of vapor. With suitable vacuum levels, drying can be cost-effective at relatively low product temperatures. Vacuum drying is particularly advantageous for heat- or oxygen-sensitive products, for reducing the risk of dust explosions, and for applications requiring solvent recovery or extremely low residual solvent levels.

A typical rotating double-cone vacuum dryer is shown in Fig. 11. Vapor exits the dryer via a tube that passes through a rotary seal along the axis of rotation. A filter prevents particles from leaving the dryer with the exiting vapor. Vacuum can be supplied by conventional pumps, blowers, or steam jets. Heating fluid circulates through a jacket and enters and exits through dynamic seals along the axis of rotation. Typical rotation speeds are 6–8 rpm. Working capacities, generally defined as 50% of total volume, range from 0.1 to 10 m^3 and vacuum levels range from just under ambient to 20 mm Hg (33). Indirect methods rely on contact between the wet material and the jacketed walls of the dryer to supply energy and the drying rate can be heat transfer-limited. Average drying rates range from 1–7 $\text{kg/h}/\text{m}^2$ of heat transfer surface area available. The ratio of jacket area to working volume tends

Fig. 11 Rotating double-cone vacuum dryer.

Fig. 12 High shear vacuum processor.

to decrease with increasing size, so larger models often require additional internal plates or pipe coils to increase available area for heat transfer (33).

Vacuum drying can be readily incorporated into high shear granulation designs to permit multiple processing steps to be completed in a single piece of equipment, as shown in Fig. 12. Granulation takes place in an initial processing step by introducing a fluid to the particle bed while mixing it with a high shear impeller. Vacuum drying follows. Typical vacuum conditions are 18–22 mm Hg. The vapor exits through a port in the cover through a tube equipped with a particulate filter. Heating fluid is circulated through the jacket of the bowl with typical operating temperatures of 60–80°C. Inert stripping gas (3–30 m³/h depending of vessel volume) is introduced through the shaft seal to improve the convective transfer of vapor out of the vessel during drying. Gas stripping rates above an optimal level reduce the drying effectiveness by raising the pressure in the vessel. Commercial designs allow for tilting of the unit up through 180° to improve contact between the granules and the heated walls. Microwave and infrared generators can be added to augment the heat transfer rates (34, 35).

Microwave (Dielectric) Drying

By applying microwave energy to pharmaceutical systems to be dried, dielectric materials such as water and solvents with dissolved salts absorb the energy thereby increasing molecular vibration. This movement is in turn converted to friction resulting from interactions with neighboring molecules, solvent temperature increases and ultimately vaporizes, and drying is affected (36). In contrast to previously discussed more conventional means of drying, energy is transferred to the entire volume of solvent in a particle rather than relying on heat transfer from contact

surfaces to the interior of a particle or bed. This mode of energy transfer provides for higher temperatures at the center of the granule or powder bed, generating a temperature gradient directed outward from the center of the material. This facilitates both liquid and vapor mass transfer away from the center of the granule. Vaporization of the solvent inside the granule can occur (36), which allows drying rates to be governed by the diffusion coefficient of the solvent vapor rather than that of the liquid, potentially reducing mass transfer limitations in drying rate.

Microwave dryers can be constructed as stand-alone cabinets, as combination dryers with vacuum, fluid bed, or vibrational capabilities, and as one-pot processors that provide mixing and granulation capabilities in conjunction with microwave drying. Microwaves are generated at typical frequencies of either 915 MHz or 2.45 GHz, and are directed to the powder bed to be dried by way of waveguides. The magnetrons used to generate the microwave output require high-voltage supply and may require water cooling to remove excess heat. The size (output) and number of magnetrons depends on the size of the dryer and mass of wet material to be dried, and in many applications are pulsed on and off by a controller to prevent damage to the product resulting from excessive heat generation.

Some dryers also provide heat energy to the powder mass by a jacketed vessel, thereby increasing overall heat transfer. Moisture can be removed via vacuum or hot air fluidization depending on the design of the dryer allowing for improved evaporative drying and vapor mass transfer. Fig. 13 shows the relationship between power input (W) and first-order drying rate constant in a microwave fluid-bed processor (37).

Fig. 13 The influence of microwave power input and inlet air temperature on microwave fluid-bed drying. (From Ref. 37.)

The extent of microwave drying can be correlated to the amount of power absorbed by the product, which is described by Eq. 44 (38):

$$P = 2\pi f V^2 E_0 E_r \tan \delta \quad (44)$$

where P is the power density (W/m^3), f is the frequency (Hz), V the voltage gradient (V/m), E_0 the dielectric constant of vacuum ($8.85 \times 10^{-12} \text{ F/m}$), E_r the dielectric constant of the material being dried (F/m), and δ is the loss angle (a physical property of magnetic waves).

The product of the dielectric constant and the loss tangent ($\tan \delta$) is called the *loss factor* (36), E_r'' , and is a relative measure of how easily a material will be heated by microwave energy.

$$E_r'' = E_r \tan \delta \quad (45)$$

A table of loss factors of some common solvents and excipients are given in Table 3.

Clearly the composition of the powder to be dried plays an integral role in the drying process, using microwaves based on the energy absorption characteristics a formulation possesses. As microwaves penetrate the powder bed the intensity of the electrical field strength is reduced by absorption according to when

$$d = \frac{\lambda_r E_r^{1/2}}{2\pi E_r''} \quad \text{when } E_r'' \ll 1 \quad (46a)$$

or when

$$d = \frac{\lambda_r}{2\pi (E_r'')^{1/2}} \quad \text{when } E_r'' \gg 1 \quad (46b)$$

where d is the depth where the field strength is 37% (or $1/e$) of original value, and λ_r is the wavelength (e.g., 12.3

Table 3 Comparison of loss factors of some common pharmaceutical materials

Material	Loss factor, E_r''
Methanol	13.6
Ethanol	8.6
Water	6.1
Isopropanol	2.9

cm at a frequency of 2450 MHz). Fig. 14 shows the calculated penetration depth for lactose and starch.

Because the penetration depth is limited, both the speed and the uniformity of drying can be improved by mixing during the drying process. As a material loses moisture during the drying process, both its dielectric constant and its loss tangent change. Because the loss factor is the product of these numbers, an understanding of these property characteristics throughout the drying process may be important. For example, starch with 3% moisture has a higher loss factor than it does with both 7.5% and 15% moisture (39).

Theoretical comparisons have been made between conventional drying techniques and microwave and have shown the superior drying rate of microwave over conductive drying in a jacketed bowl (39) and microwave-aided fluid bed-drying over fluid bed-drying alone (40). Because of the reduced drying time associated with the use of increased microwave energy, the generation of pharmaceutical dust can be reduced in a single-pot drying process (41).

Because of the benefits in drying uniformity and efficiency in energy transfer, microwave drying provides an attractive alternative to more conventional modes of drying. For highly potent pharmaceutical compounds the microwave unit provides a high degree of containment (particularly when coupled with high shear granulation) and is an easily cleanable dryer. However, the initial capital investment to install such a dryer and the significant amount of ancillary equipment is oftentimes prohibitive in conventional applications. Nonetheless, uniformity in drying and reduction in time and manpower may be sufficient to consider microwave drying as a viable alternative.

ECONOMIC CHARACTERISTICS OF THE R&D-INTENSIVE PHARMACEUTICAL INDUSTRY

Douglas L. Cocks

Indiana University, Bloomington, Indiana, U.S.A.

INTRODUCTION

This article presents a brief sketch of the economics of the R&D-intensive ethical pharmaceutical industry, highlighting its dynamic characteristics. The approach taken here minimizes the use of static analysis, and thus avoids the use of pure or perfect competition as an analytical tool. In this theoretical discussion, certain empirical studies will be cited as support for aspects of the theory being developed.

The theory discussed here will concentrate on allocative efficiency, but as with all discussions of allocative efficiency, elements of technical efficiency will automatically be involved and at least implicit recognition of these elements will be evident. The allocative efficiency concerns will be placed in a dynamic framework; we will be attempting to establish a notion of "dynamic pure competition" that has analytical and public policy implications. The concept of dynamic pure competition will describe a hybrid form of workable competition as the term is used by industrial organization economists.

AN OUTLINE OF A COMPETITIVE PROCESS

Before we get into an outline of the theory of pharmaceutical economics, we need to establish pure competition as a *competitive process*. Traditional microeconomics has assumed implicitly that the "natural state" is one that is depicted by pure competition. Deviations from the natural state occur as a disequilibrium, by the establishment of monopoly power, or through other often cited market failures. In cases of disequilibrium, the tatonnement will bring us to the equilibrium ideal of pure competition. Interestingly, the model of pure competition never really describes the process of the tatonnement (equilibration) but only the conditions necessary for the process to operate and the final equilibrium to result when the process has worked itself out.

The monopoly power deviation arises because the nature of "economic man" causes him or her to attempt to break out of a pure competitive equilibrium, or the equilibrating tatonnement process, and maximize his or her own economic situation relative to the rest of the world. The economic man will attempt to establish a monopoly power position through "entry barrier" means (1a, 1b).

According to traditional microeconomics, then, the natural economic process is one that proceeds from the natural state of pure competitive equilibrium, or from where the necessary conditions exist for the pure competitive tatonnement process to take place, to conditions of monopoly.

The competitive process that is relevant here is one in which a naturally occurring monopoly is systematically faced with a pressure that erodes this position. It is a process that occurs on a continuum and which must be considered on the basis of changes through time. Reverting to the static sense, the economic concept of deadweight welfare loss is a representation of the social opportunity cost that is associated with having entrepreneurs, singular and corporate, invading previously held monopoly positions by providing new and improved products and services. This in turn represents the economic progress that generates welfare gains, in the technically economic context and not in the sense of providing public funds to needy populations. Through time, economic life is characterized as a continual process of monopoly establishment and systematic erosion via entrepreneurial activity. This entrepreneurial activity constitutes the observation of, and action upon, profit opportunities as evidenced by static monopoly rents.

We can think of dynamic pure competition as a process where naturally occurring monopoly is systematically eroded. It represents a kind of entropy that properly allocates resources in the production of current and future goods and services. The underlying characteristics of the competitive process are that it recognizes that economic imperfections are inherent; that economic man realizes this as a matter of course; and he or she is willing to

compensate economic agents who act to ameliorate these imperfections.

EMPIRICAL EVIDENCE OF COMPETITION IN THE PHARMACEUTICAL INDUSTRY

The issue of competition in the pharmaceutical industry is implicitly addressed in the works of Cocks and Virts (2, 3), who show a significant lack of price rigidity in various drug markets and among individual drug products. But its clearest discussion is given by Brozen (4):

The Cocks data also destroy the common fiction of rigid prices for drugs and the fiction of inelastic demands for each of these patented products. Prices are remarkably flexible, thus producing large effects on market position. Leading products in the anti-infective market, for example, suffered price declines from 1962 to 1971 ranging from 7% (for product number 8) to 67% (for product number 3). The average price decline in this inflationary period for these products was 32%, while the consumer price index rose 34%. The price of leading anti-infectives fell by 51% in constant dollars. This is a remarkable record.

Sales of these products also demonstrate what a complete fiction is the story that the average physician pays no attention to prices in writing prescriptions. Product 11 among the anti-infectives languished at 0.1% of the market for 5 years until it had cut its price by 47%. At that point, its market share rose to 0.7%, a sixfold increase. Another 14% price cut raised its market share another 170%. Still further cuts over the next three years amounting to 12% raised its market share by still another 68%. This would seem to demonstrate a remarkably high price elasticity of demand for a branded patented product; particularly in view of the price cuts of competitive products.

Product number 3 had a fading market position from 1962 through 1969 "despite its price cuts, but then a 16% price cut in 1970 stopped the decline and added 14% to its market share. A further 27% cut in 1971 jumped its market share by another 40%. The market for ethical drugs responds remarkably vigorously to price changes, the myth of the price-insensitive prescribing physician to the contrary notwithstanding.

There appears to be competition among products within each class despite whatever unique features

each possesses. A product only singular enough to win 0.1% of the market over a five-year span won a 310% increase in market share when it cut its price relative to most of the other products in its market. A fading product turned itself around and reclaimed a major portion of its market position as it undertook similar price action."

One area that has been emphasized in economic theory is that price competition does not exist if a firm or group of firms can charge different prices to different segments of the market. In the pharmaceutical industry, this "market failure" has been emphasized relative to the prices charged to the elderly. It has been claimed that the elderly pay higher prices than the rest of the population. A recent study by Berndt et al. provides statistical evidence that the elderly do not.

A study by Reekie provides a more systematic analysis of pricing behavior regarding pharmaceutical products (5). This study provides a statistically strong inference that physicians are indeed sensitive to drug prices. The paper provides statistical evidence on pharmaceutical product price elasticity in which the coefficient of elasticity is determined to be greater than 1. Schwartzman also provides significant evidence on the amount of price competition in the pharmaceutical industry, especially in the area of antibiotics (6). The elderly generally pay higher prices than the rest of the population, and in some drug categories they pay lower prices (7).

INTERNAL ORGANIZATION CHARACTERISTICS OF THE PHARMACEUTICAL FIRM

The model of the pharmaceutical firm that we have constructed so far leaves us with a fundamental dichotomization of the firm. The dichotomy is between the firm consisting of the production of existing, marketed products, and the production of new products through research and development. The existence of this naturally leads us to question why the firm has to consist of these seemingly different activities. In other words, why could there not be firms who engage in research and development and only produce new products? They could sell these new products on the open market to firms whose specialized function it is to produce and sell the products developed by research firms. In addressing this issue, it is hoped that greater insight into the subtleties of the theory of the pharmaceutical firm can be garnered.

There are two basic elements as to why it is economically efficient to have both characteristics—current product production and new production—present

in one firm. The first element relates to corporate finance and the sources and uses of cash flows in the firm. The second element relates to the efficiencies that can be gained by resorting to markets within the firm (as opposed to external markets that are thought of in conventional microeconomic theory) (8a, 8b, 8c). It should be obvious from the discussion that follows there is an inherent interaction between these elements. This discussion also points out the entrepreneurial function in the firm and its implications for considering the efficiency of the firm.

A characteristic of the pharmaceutical industry, and very likely other R&D-intensive industries, is the interrelationship among new products, the cash flows of the firm, profit expectations, and the utility-enhancing characteristics of new drugs. This flow of economic events can be depicted in the following:

This is a series of events that occurs on a continuum, and the main characteristic is the internally generated cash flows that provide the wherewithal for R&D investment to come from the portfolio of existing products. To provide the necessary cash flows, this portfolio must contain products that have a range of price-marginal manufacturing cost differentials.

The relevance of the two elements, just discussed, can be elaborated on by considering the employment relation that is the primary aspect of the R&D process described above. Pharmaceutical R&D is really an investment in and accumulation of human capital through the employment of scientists and technicians. Like all human capital its “producing” aspects are necessarily embodied in individuals. Unlike normal labor (6) and any associated human capital characteristics that go with it (learning by doing), the human capital associated with pharmaceutical R&D creates

complexities of monitoring and metering work effort. These difficulties exacerbate the contingent claims contracts, bounded rationality, opportunism, and information impactedness problems that would prevail if external markets were used. The use of a hierarchical system clearly presents a less costly alternative. In addition, it is evident from the previous description of the R&D process that the internal market organization allows the combining of the R&D inputs and yields output that is larger than the sum of the products if inputs are used separately.

We can now address the significance of a third element—what can be described as the entrepreneurial, combined element. The six stages of the R&D system process are really the steps that characterize going from invention to innovation, as discussed in the economics of innovation literature. The role of the concept of the entrepreneur is very crucial here. If we view the entrepreneur as the economic visionary, the importance of his or her role is especially apparent in stage 1 of our stage process. At this stage something more than mere “scientific” ability is required. It is also necessary to have the vision to convert “science” or knowledge into a useful product. However, each step of the system process requires entrepreneurial input.

The pharmaceutical firm amalgamates the diverse entrepreneurial activities that make up the complex process from invention through getting a marketable pharmaceutical product. In essence, we are making a distinction between the R&D inputs: scientist and scientist-entrepreneur. In many cases, the scientist does not have the full extent of entrepreneurial ability, and the firm provides the mechanism to achieve this. In addition, when dealing with both the scientist and scientist-entrepreneur, the problems with the Williamson (9) concepts are attenuated; resources are economized because the elements of complexity of contingent claims contracts, bounded rationality, information impactedness, and opportunism are separately prevalent in both the scientists’ and scientist-entrepreneurs’ activities. It is likely that there are distinctive aspects of the Williamson characteristics that are interactive, and this compounds the difficulties and thus makes the internal organization alternative less resource-costly.

In summary, the pharmaceutical R&D process lends itself to the efficiency gains that come from internally organizing these activities. These efficiencies are derived from the existence of the complex technological environment that surrounds the R&D process.

The essence of the theory that we are attempting to apply to the pharmaceutical industry has clearly been outlined by Demsetz. The crucial point is that there are

efficiency gains that are apparent not by comparing them with some ideal, but by comparing them with "real world" alternatives (10).

CONCLUSIONS

The model of the economics of the pharmaceutical industry that is developed here has four basic assumptions:

1. There is price sensitivity on the part of pharmaceutical consumers or, in particular, their agents-physicians, for new products as well as for existing products.
2. Research and development (R&D) serves as the primary catalyst for change among drug firms and is the focal point of entrepreneurial activity that ensures dynamic welfare gains (a continuum of static welfare losses being offset by concomitant higher utility, yielding benefits from new products and systematic erosion of monopoly power through price pressures for older products). As an institutional consideration, there will be a substantial number of firms intensively engaged in R&D activity. In the late 1990s there have been attempts at mega mergers in the industry that would create firms approaching the \$100 billion or more sales amount. These mergers seem to be due to the significant rise in the R&D cost of developing new drugs—possibly exceeding \$500 million.
3. The utility benefits from even small improvements in therapy can theoretically offset substantial differences in the prices of the new improvement relative to existing drug therapies. (This is basically a corollary to assumption 2).
4. The economic profitability of the industry will reflect all dynamic opportunity costs and will through time tend toward normal returns. As such, economic profitability serves as the ultimate guide to the proper allocation of resources as it does with the pure competitive model.

It has been the purpose of this article to apply certain aspects of economic analysis to the pharmaceutical industry. In doing this, we have described a dynamic competitive process that generates new products and

serves as a mechanism that pushes us toward the optimal allocation of resources for the production of existing products. A model of the pharmaceutical firm was also presented. Finally, the welfare implications of the competitive process and the model of the firm were discussed.

EMULSIONS AND MICROEMULSIONS

Gillian M. Eccleston

University of Strathclyde, Glasgow, United Kingdom

EMULSIONS

An emulsion is a heterogeneous preparation composed of two immiscible liquids (by convention described as oil and water), one of which is dispersed as fine droplets uniformly throughout the other. Emulsions are thermodynamically unstable and revert back to separate oil and water phases by fusion or coalescence of droplets unless kinetically stabilized by a third component, the emulsifying agent. The phase present as small droplets is called the disperse, dispersed, or internal phase and the supporting liquid is known as the continuous or external phase. Droplet diameters vary enormously, but in pharmaceutical emulsions they are typically polydispersed with diameters ranging from approximately 0.1 to 50 μm . Emulsions are conveniently classified as oil-in-water (o/w) or water-in-oil (w/o), depending on whether the continuous phase is aqueous or oily. Fig. 1a shows a photomicrograph of a simple o/w system. Practical pharmaceutical emulsions, however, are rarely simple two-phase oil and water preparations; many are multicomponent systems containing additional solid or liquid crystalline (e.g. lamellar) phases (Fig. 1b). Multiple emulsions, which are prepared from oil and water by the reemulsification of an existing emulsion so as to provide two dispersed phases, are also of pharmaceutical interest. Multiple emulsions of the oil-in-water-in-oil (o/w/o) type are w/o emulsions in which the water globules themselves contain dispersed oil globules; conversely, water-in-oil-in-water (w/o/w) emulsions are those where the internal and external aqueous phases are separated by the oil (Fig. 1c). These more complex emulsions are covered by the broader International Union of Pure and Applied Chemistry (IUPAC) definition of emulsions, which extends the classical definition to include "liquid droplets and/or liquid crystals dispersed in a liquid" (1).

Emulsions are formulated for virtually all the major routes of administration, and there are a number of dermatological, oral and, parenteral preparations available commercially. The internal phase may contain water-soluble drugs, preservatives, and flavoring agents whilst the oil phase may itself be therapeutically active or may act as a carrier for an oil-soluble drug. Such preparations

provide an effective approach to many of the problems in drug delivery, often showing distinct advantages over other dosage forms by way of improved bioavailability and/or reduced side effects. However, despite such advantages, emulsions are not used as extensively as other oral or parenteral dosage forms due to the fundamental problems of emulsion instability that result in unpredictable drug release profiles and possible toxicity. The full potential of emulsions will not be realized until stable systems are developed with predictable *in vitro* and *in vivo* release patterns. Much of the emulsion research over the past decade is based on attempts to understand the relationships between emulsion stability, physicochemical properties, and biological fate. Multiple emulsions are even more difficult to stabilize, and characterize and although there is an increasing interest in their potential applications for drug delivery, at present there are no commercial preparations available (2).

PHARMACEUTICAL APPLICATIONS

The current and potential pharmaceutical applications of emulsions have been the subject of a number of general reviews (3–6). Traditionally the term "emulsion" is restricted to mobile emulsions for internal use; emulsions for external use are described by their pharmaceutical types as liniments, lotions, and creams. This tends to conceal the fact that by far the largest group of emulsions currently used in pharmacy and medicine are dermatological emulsions for external use (7, 8). Both oil-in-water and water-in-oil emulsions are extensively used for their therapeutic properties and/or as vehicles to deliver drugs and cosmetic agents to the skin. The emulsion facilitates drug permeation into and through the skin by its occlusive effects and/or by the incorporation of penetration-enhancing components. Particular attention is paid to patient acceptance of such formulations, which range in consistency from mobile liniments and lotions to semisolid ointments and creams. In the past, the development of dermatological emulsions was essentially empirical with only a limited understanding of the

Fig. 1 Photomicrographs of typical emulsions. (a) A liquid paraffin-in-water emulsion stabilized by 1.89% Span 40 and 1.62% Tween 80. The polydispersity of the oil droplets before homogenization is clearly seen. (b) A liquid paraffin–water cream stabilized by a cationic emulsifying wax. Note the lamellar structures surrounding the oil droplets. (c) A multiple w/o/w emulsion. Water droplets can clearly be seen within the larger oil droplets.

underlying principles. Today, although the microstructure of many of these complex formulations is now better understood (9, 10), the mechanisms by which the structure of an emulsion can influence drug bioavailability are far from clear and much of the literature on the role of emulsions in drug release to the skin is contradictory. Confusion arises because the majority of investigations concerning in vitro vehicle effects on drug release are only on bulk formulation. As most emulsions are applied to the skin as a thin film, the drug delivery system is not one of bulk emulsion, but rather a dynamic evaporating system in which phase changes can occur as the preparation is rubbed into the skin and the relative concentrations of volatile ingredients alter. Droplet size appears to influence drug delivery to the skin, with submicron lipid emulsions enhancing the transcutaneous permeation and efficiency of a number of lipophilic drugs (11).

Oral emulsions are almost exclusively of the oil-in-water type. They provide a degree of taste masking as the aqueous external phase effectively isolates the oil from the tongue. Mineral and castor oils have been emulsified in water and administered orally for the local treatment of constipation for many years (cf. Mineral Oil Emulsion USP) as have various nutritional oils from fish liver (generally halibut or cod) or vegetable origin to produce oral liquid food supplements. It has long been established that the use of o/w emulsions as carriers for lipophilic drugs may improve oral bioavailability and efficacy (3–6). For example, griseofulvin formulated as an o/w emulsion has enhanced gastrointestinal absorption when compared with suspensions, tablets, or capsule dosage forms (12). The mechanisms by which emulsions modify and improve

absorption processes are complex and not fully understood, although the oil itself influences gastric motility. Fats and oils are solubilized by the bile salts so that the administration of already emulsified oil droplets containing a high concentration of drug may increase the likelihood of further droplet and drug solubilization and transport across the GI tract by the fat absorption pathways.

The type of emulsion used parenterally depends on the route of injection and the intended use (13–15). Oil-in-water emulsions are administered by all the major parenteral routes whereas water-in-oil emulsions are generally reserved for intramuscular or subcutaneous administration where sustained release is required. Drug action is prolonged in such oily emulsions because the drug has to diffuse from the aqueous dispersed phase through the oil-continuous environment to reach the tissue fluids. Water-in-oil emulsions are used to disperse water-soluble immunizing antigens in mineral oil for injection via subcutaneous or intramuscular routes as adjuvant preparations where they prolong and enhance the antigenic stimulus and increase the antibody titer. Oily emulsion formulations also show promise in cancer chemotherapy as vehicles for prolonging drug release after intramuscular or intratumoral injection, and as a means of enhancing the transport of anticancer agents via the lymphatic system (16). Water-in-oil emulsions for sustained release are often difficult to inject because of the high viscosities of the oily continuous phases. Although these problems can be overcome by reemulsification of the primary w/o emulsion to produce a less viscous multiple w/o/w emulsion, a study using

Table 1 Some commercial lipid emulsions for parenteral nutrition

Trade name	Oil phase (%)	Emulsifier (%)	Other components (%)
Intralipid [®] (Fresenius Kabi)	Soybean (10 and 20)	Egg lecithin (1.2)	Glycerol (2.2), phosphate (15mm/l)
Lipovenos [®] (Fresenius Kabi)	Soybean (10 and 20)	Egg lecithin (1.2)	Glycerol (2.5)
Liposyn [®] (Abbott)	Safflower and soybean, 1:1 (10 and 20)	Egg lecithin (1.2)	Glycerol (2.5)
Lipofundin [®] (Braun)	Cottonseed (15)	Soybean lecithin (0.75)	Sorbitol (5.0), DL- α -Tocopherol
Lipofundin N [®] (Braun)	Soybean (10 and 20)	Egg lecithin (0.75 and 1.2)	Glycerol (2.5)
Lipofundin MCT/LCT [®] (Braun)	Soybean and MCT, 1:1 (10 and 20)	Egg lecithin (0.75 and 1.2)	Glycerol (2.5)

5-fluorouracil implied that sustained release was actually less marked with multiple emulsions (17).

Sterile parenteral oil-in-water emulsions have been used extensively for over 40 years for the intravenous administration of fats, carbohydrates, and vitamins to debilitated patients. Several vegetable oil-in-water emulsions are now available commercially with droplet sizes similar to that of chylomicrons (approximately 0.5–2 μm), the natural fat droplets in the blood that transport ingested fats to the lymphatic and circulatory systems (Table 1). More recently, such emulsions have been employed as intravenous carriers for poorly water-soluble lipophilic drugs such as vitamin K (e.g., Sterile Phytonadione Injection U.S.P.) diazepam (e.g., Diemuls[®]), vitamin A (Vitlipid N[®]), and profenol (Diprovan[®]) as alternatives to the traditionally used cosolvent, surfactant solubilized, or pH controlled parenteral solutions. The drug dissolved in the oil phase of the emulsion is unlikely to precipitate and cause pain when diluted by blood on injection, and if susceptible to hydrolysis or oxidation, it will be protected by the nonaqueous environment. Emulsion formulations of diazepam and more recently clarithromycin have been clinically shown to be less painful than solubilized preparations (18, 19) while emulsions containing amphotericin B are less toxic (20). This emulsion was also shown to be an equally effective, cheaper, and more elegant alternative to a liposomal system. The enormous literature on the potential of lipid emulsions for drug delivery and targeting is discussed in a recent book (21).

Radiopaque emulsions, which have long been used as contrast media in conventional X-ray examinations of body organs, are finding further application with more sophisticated techniques including computed tomography, ultrasound, and nuclear magnetic resonance. Perfluorochemical emulsions are used as artificial blood

substitutes. The potential advantages of such systems over donated blood are enormous with the elimination of major donor associated problems such as blood group incompatibilities and blood disease. The first commercial product, Fluosol-DA[®] (Green Cross Corporation, Osaka, Japan) was licensed several years ago in a number of countries to reduce myocardial ischaemia in patients undergoing angioplasty; however, Fluosol-DA was not a commercial success due to its slow excretion rate and to its marked instability, which meant that it had to be stored in the frozen state. In addition, some patients were sensitive to one of the emulsifiers, pluronic F68[®]. Currently, a second generation of emulsions is being evaluated to resolve the problems encountered with Fluosol (22) and these are discussed in another chapter of this encyclopedia.

There are only a few studies on the ocular and nasal applications of emulsions. Lipid (submicron) emulsions exhibited a long-lasting antidepressant effect on the intraocular pressure of rabbits after a single application when used as carriers for lipophilic antiglaucoma drugs (23). Medium-chain triglyceride emulsions formulated at pH 8 show potential as controlled release formulations for nasal delivery (24, 25) for they give prolonged drug residence in the nasal cavity (Fig. 2). Enhanced nasal delivery of insulin was observed when insulin was incorporated into the continuous phase of an o/w emulsion, but not when incorporated into the aqueous phase of a w/o emulsion (26).

FORMULATION CONSIDERATIONS

The choice of oil, emulsifier, and emulsion type (o/w, w/o, or multiple) is limited by its ultimate use and route of

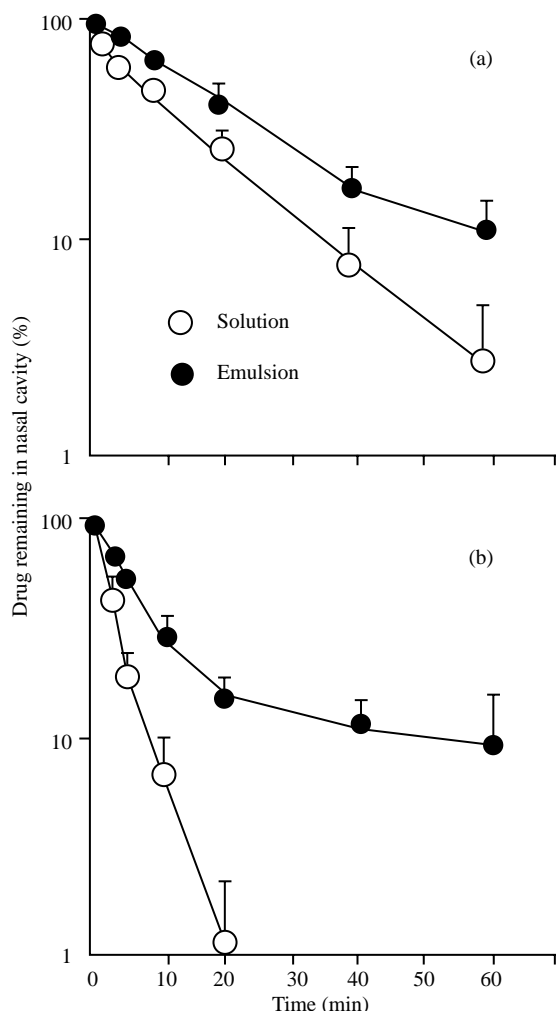

Fig. 2 Disappearance profiles of (a) tetrahydrozoline hydrochloride and (b) chlorpheniramine maleate from rat nasal cavity after nasal administration of an o/w emulsion and an aqueous solution at pH 8. (From Ref. 25.)

administration. Potential toxicity and chemical incompatibilities in the final formulation must be taken into account as must processing details for these also affect the variables that control emulsion stability and therapeutic response such as droplet size distributions and rheology. The design of stable emulsions with the correct pharmacokinetic characteristics and tissue distribution is currently an area of enormous interest, particularly for parenteral IV emulsions. Immediately after injection, the surface of the parenteral emulsion droplets is altered by adsorption of blood components (optosonation) and they are then distributed rapidly through the circulation. Their subsequent fate depends on whether they are treated by the body in the same manner as chylomicrons, or whether they

are recognized as foreign particles and cleared by the RES. Many factors, including droplet size and charge, the type of lipid, and the emulsifier composition influence their fate. A major factor to be considered in the formulation of oral preparations is the low pH and high ionic strength of stomach fluids, which may destabilize the emulsion by its effect on the emulsifier.

Pharmaceutical Oils

Oils used in the preparation of pharmaceutical emulsions are of various chemical types, including simple esters, fixed and volatile oils, hydrocarbons, and turpenoid derivatives. The oil itself may be the medicament, it may function as a carrier for a drug, or even form part of a mixed emulsifier system as in the case of some fixed oils that contain sufficient free fatty acids. Many oils, particularly those of vegetable origin, are liable to autooxidation with subsequent rancidity, and it is frequently necessary to add an antioxidant and/or preservative to inhibit this degradation process. For externally applied emulsions, mineral oils, either alone or combined with soft or hard paraffins, are widely used both as the vehicle for the drug and for their occlusive and sensory characteristics. The most widely used oils in oral preparations are nonbiodegradable mineral and castor oils that provide a local laxative effect, and fish liver oils or various fixed oils of vegetable origin (e.g., arachis, cottonseed, and maize oils) as nutritional supplements.

The choice of oil is severely limited in emulsions for parenteral administration for reasons of toxicity. Purified soybean, sesame, safflower, and cottonseed oils composed mainly of long-chain triglycerides have been used for many years as they are resistant to rancidity and show few clinical side effects. More recently, it has been recognized that the structure of the oil will influence the fate of emulsion droplets after injection. Mixtures containing both long- and medium-chain triglycerides are not only better energy sources for nutritional purposes but they are also cleared more rapidly from the circulation (27); such mixtures are now used in commercial preparations (c.f. Table 1). Structured triglycerides, formed by modifying the oil enzymatically to produce 1,3-specific triglycerides are an area of increasing interest because of their influence on the in vivo circulation time of an emulsion (28). Purified mineral oil is used in some water-in-oil depot preparations where mineral toxicity (e.g., abscess formation at the injection site) must be carefully balanced against efficiency. Emulsified perfluorochemicals are considered acceptable for IV use provided that they are

excreted relatively fast. A major problem in the formulation of the early perfluorocarbon emulsions was that the oils that form the most stable emulsions were not cleared rapidly from the body.

Pharmaceutical Emulsifiers

Emulsifying agents are used both to promote emulsification at the time of manufacture and to control stability during a shelf life that can vary from days for extemporaneously prepared emulsions to months or years for commercial preparations. In practice, combinations of emulsifiers rather than single agents are used. The emulsifier also influences the *in vivo* fate of lipid parenteral emulsions by its influence on the surface properties of the droplets and on the droplet size distributions. For convenience, most pharmacy texts classify emulsifiers into three groups: i) surface active agents, ii) natural (macromolecular) polymers, and iii) finely divided solids.

Surface Active Agents

The range of surfactant emulsifiers used in pharmaceutical preparations is illustrated in Table 2. Surfactants are manufactured from a variety of natural and synthetic sources and consequently they show considerable batch-to-batch variations in their homologue compositions and in trace impurities from the starting material. For example, batch variations in the number of neutral phospholipids occur in lecithin surfactants and nonionic polyethylene surfactants show variations in the number of moles of ethylene oxide. The mechanisms by which such batch variations lead to differences in emulsifying properties are now better understood (29).

Although synthetic and semisynthetic surfactants form by far the largest group of emulsifiers studied in the scientific literature and many of them are available commercially, their use in pharmaceutical emulsions is limited by the fact that the majority are toxic (i.e., haemolytic) and irritant to the skin and mucous

Table 2 Synthetic surface active emulsifying agents

Class	Example	Type	Compatibility
Anionic			Efficient to various degrees above pH 7; incompatible with cationic surfactants and polyvalent cations
Alkali and ammonium soaps	Sodium stearate	o/w	
Divalent and trivalent metallic soaps	Calcium oleate	w/o	
Organic sulfates	Sodium lauryl sulfate	o/w	
Cationic			Efficient below pH 7; incompatible with anionic surfactants and polyvalent anions
Quaternary ammonium compounds	Cetrimonium bromide	o/w	
Pyridium compounds	Hexadecyl pyridinium chloride	o/w	
Nonionic			Efficient to various degrees over pH range 4–8; good tolerance to ionic surfactants and polyvalent ions
Alcohol polyethylene glycol ethers	Ceteth 20	o/w	
Fatty acid polyethylene glycol esters	Polyethylene glycol 40 stearate	o/w	
Ethoxylated fatty acid polyethylene glycol esters	Sorbitan mono-oleate (Span 80)	w/o	
	Polyoxyethylene sorbitan monooleate (Tween 80)	o/w	
Polymeric			
Polyoxyethylene-polyoxypropylene block co-polymers	Poloxomers, Pluronic F-68®	o/w	
Amphiphiles			Generally used combined with a surfactant to form a o/w emulsion
Fatty alcohols	Cetyl alcohol	w/o	
Fatty acids	Stearic acid	w/o	

membranes of the gastrointestinal tract. In general, cationic surfactants are the most toxic and irritant and nonionic surfactants the least. Surfactants are therefore used mainly at relatively low concentrations in topical preparations. The quaternary ammonium compounds constitute an important group of cationic emulsifiers in dermatological preparations because they have antimicrobial properties in addition to their o/w emulsifying action. There are many nonionic surfactants with different oil and water solubilities available commercially because for each fatty starting material the polyoxyethylene chain length can be modified by the systematic addition of ethylene oxide groups. However, a limited number of polysorbate surfactants are used in oral emulsions, and parenteral preparations appear to be based only on the lecithins from plant or animal sources and the nonionic polyoxyethylene oxide/polyoxypropylene oxide block copolymer poloxamer 188 (Poloxamer F68[®]), although some patients using the first generation of perfluorochemical emulsions were sensitive to this poloxamer. The emulsifier influences both emulsion stability and in vivo disposition by its influence on droplet surface properties.

Natural macromolecular materials and finely divided solids

Materials derived from natural sources (Table 3) may originate from animal or vegetable sources and many of these products are susceptible to degradation. For example, depolymerization (the polysaccharides) or hydrolysis (the steroids) usually lead to loss in emulsifying power. Some of these materials, polysaccharides and proteins in particular, provide good culture medium for microorganisms, and therefore preservation of emulsions containing them is imperative. To overcome

these problems, a number of purified and semisynthetic derivatives are available, including various purified wool fat derivatives and semisynthetic celluloses such as methylcellulose and sodium carboxymethylcellulose. These are generally more stable than the unmodified materials. These celluloses are used in oral preparations; they are less suitable for topicals because of their unpleasant feel. Finely divided solids such as clays are used in dermatological preparations as structuring agents.

Preservatives

It is essential that emulsions are formulated to resist microbial attack, as this not only can affect the physicochemical properties of the formulation, causing color, odor, or pH changes and even phase separation, but may also constitute a health hazard. The potential sources of contamination can be from raw materials (especially if these are natural products), water, manufacturing and packaging equipment, or patients themselves. W/o emulsions are less susceptible to attack than o/w emulsions because the aqueous continuous external phase can produce ideal conditions for the growth of bacteria, moulds, and fungi. Preservatives are not used in parenteral emulsions, which are sterilized, generally by autoclaving, but sometimes by using sterile components and aseptically assembling the final emulsion.

There is no simple way of predicting the ideal preservative for a particular emulsion. In addition to requiring a wide spectrum of activity against bacteria, yeasts, and molds, the preservative should be free from toxic, irritant, or sensitizing activity. Some commonly used preservatives in oral and topical preparations include phenoxyethanol, benzoic acid, parabenzates, and chlor-cresol. Emulsions are heterogeneous products, and the

Table 3 Emulsifying agents derived from natural products and finely divided solids

Class	Example	Emulsion type, route of administration	Comments
Polysaccharide	Acacia	o/w; oral	Stable over a wide pH range
	Carageen	o/w; oral	As above
	Methylcellulose	o/w; oral, parenteral	As above, less prone to hydrolysis
Protein	Gelatin	o/w; oral,	Emulsifying properties pH dependent
Glycoside	Saponin	o/w; topical	
Phospholipid	Lecithin	o/w; oral, parenteral	Emulsifying properties dependent on number of negative lipids
Sterol	Wool fat	w/o; topical	Poor emulsifiers alone
	Cholesterol and its esters	w/o; topical	As above
Finely divided solids	Bentonite	o/w and w/o; topical	Gelation dependent on processing conditions
	Veegum	o/w; oral, topical	As above
	Aluminium hydroxide	o/w; oral	

preservative partitions between the oil and aqueous phases. As a sufficient aqueous concentration of the active (usually unionized) form must be present to ensure proper preservation, pH is an additional factor to be considered. Problems often arise because many of the materials used in emulsion formulation, for example hydrocolloids or polyoxyethylene surfactants, can interact with the preservatives, thus depleting their activity. The use of a single preservative is often considered unrealistic, and attention is being increasingly focused on the use of mixtures for a wider spectrum of activity, although this may introduce additional compatibility problems.

Antioxidants and Humectants

Antioxidants are added to many pharmaceutical preparations to prevent oxidative deterioration on storage of the oil, emulsifier, or the drug itself. Such deterioration, as well as destabilizing the formulation, imparts an unpleasant odor or taste. Some oils are supplied containing antioxidants already. Those commonly used in pharmacy include butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) at concentrations up to 0.2%, and the alkyl gallates. Humectants such as propylene glycol, glycerol, and sorbitol (5%) are often added to dermatological preparations to reduce the evaporation of water from the emulsion during storage and use. They are sometimes claimed to prevent evaporation of water from the surface of the skin, although their use at high concentrations would be expected to have the opposite effect (i.e., remove moisture and dehydrate the skin).

EMULSION FORMATION

There are essentially two major considerations in emulsification: first, the formation of emulsions of the correct type, oil-in-water, water-in-oil, or multiple emulsion with the required droplet size distributions and second, the stabilization of the dispersed droplets so formed. When given amounts of two immiscible liquids are mixed or mechanically agitated in the absence of other additives, both phases tend to form droplets of various sizes. The size distributions are related to the forces involved during the agitation process, and the number of droplets of each liquid depends on its relative volume. The surface free energy of the system, which is dependent on both total surface area and interfacial tension is raised by the increase in surface area produced during dispersion, and the system is thermodynamically unstable. To reduce this, high-energy droplets first assume a spherical shape, as this gives the

minimum surface area for a given volume, and then on collision the droplets will coalesce (fuse) to reduce the interfacial area, the interfacial tension remaining constant.

The type of emulsion that forms, either o/w or w/o, depends on the relative rates of coalescence of each type of droplet, with the more rapidly coalescing droplets forming the continuous phase. Generally, this is the liquid present in the larger amount because higher number of droplets increase the probability of collision and coalescence. With phase volumes of oil and water close to 50%, other factors such as the order and rate of addition of each liquid are important. If agitation ceases, coalescence will continue until complete phase separation—the state of minimum free energy—is reached. Thus, emulsification can be considered as the result of two competing processes, namely the disruption of bulk liquids to produce fine droplets and the recombination of the droplets to give back the original bulk liquids. With the inclusion of surfactants or other classes of emulsifiers, the type of emulsion that forms is no longer simply a function of the phase volume and the order of mixing, but also the relative solubilities of the emulsifier in oil and water. In general, the phase in which the emulsifier is most soluble becomes the continuous phase (Bancroft's Rule); thus, hydrophilic polymers and surfactants promote o/w emulsions whereas lipophilic surfactants promote w/o emulsions. Preferential coalescence of the phase in which the emulsifier is most soluble occurs because when droplets collide, the emulsifier is easily displaced from the interface into the droplet, thus providing little protection against coalescence. Theoretically, the disperse phase of an emulsion can occupy up to 74% of the phase volume, and such high internal phase o/w emulsions have been produced with suitable surfactants. It is more difficult to formulate w/o emulsions with greater than 50% disperse phase because of the steric mechanisms involved in their stabilization (discussed later), and the addition of extra water sometimes causes inversion to an o/w emulsion.

Emulsion Characteristics

In general, an emulsion exhibits the characteristics of its external phase. Several methods are available for identifying the emulsion type. Dilution tests are based on the fact that the emulsion is only miscible with the liquid that forms its continuous phase. Conductivity measurements rely on the poor conductivity of oil compared with water, and give low values in w/o emulsions where oil is the continuous phase. Staining tests in which a water-soluble dye is sprinkled onto the surface of the emulsion also indicate the nature of the continuous phase. With an o/w emulsion there is rapid incorporation of the dye into

the system whereas with the w/o emulsion the dye forms microscopically visible clumps. The reverse happens on addition of an oil-soluble dye. These tests essentially identify the continuous phase and do not indicate whether a multiple emulsion has been produced. This can be resolved by microscopy.

Rheology

The rheological properties of emulsions are influenced by a number of interacting factors, including the nature of the continuous phase, the phase volume ratio, and to a lesser extent, particle size distributions. A variety of products ranging from mobile liquids to thick semisolids can be formulated by altering the dispersed phase volume and/or the nature and concentration of the emulsifiers. For low internal phase volume emulsions, the consistency of the emulsion is generally similar to that of the continuous phase; thus, w/o emulsions are generally thicker than o/w emulsions, and the consistency of an o/w system is increased by the addition of gums, clays, and other thickening agents that impart plastic or pseudoplastic flow properties. Some mixed emulsifiers interact in water to form a viscoelastic continuous phase to give a semisolid o/w cream (7).

Droplet Size Distributions

Droplet size distributions in pharmaceutical emulsions are important from both stability and biopharmaceutical considerations. The larger the particle size, the greater the tendency to coalesce and further increase droplet size. Thus, fine particles generally promote better stability. Size distributions are influenced by the characteristics of the emulsifier and the method of manufacture. From a biological point of view, fine emulsification enhances gastrointestinal absorption and whilst this is desirable with oral formulations of nutrient oils alone or with drugs dissolved in them, it may give adverse clinical effects with mineral oils that are used for a local effect and are toxic if absorbed. Droplets in emulsions used as contrast media in computed tomography are approximately 1–3 μm . Parenteral emulsions should be formulated so that the dispersed droplet sizes range from approximately 100 nm to 1 μm . In any event, sizes should never be greater than 5 μm in diameter because of the danger of pulmonary emboli. There is clear evidence that, as with other colloidal preparations, droplet size distributions influence the clearance kinetics of parenteral emulsions. Larger droplets are treated as foreign bodies and rapidly cleared by elements of the RES while smaller droplets may be treated

as natural fat sorting lipoproteins, with a different in vivo fate (30). Drug delivery from dermatological preparations also appears to be improved in lipid emulsions containing submicron droplets (11).

EMULSION STABILITY

A stable emulsion is considered to be one in which the dispersed droplets retain their initial character and remain uniformly distributed throughout the continuous phase for the desired shelf life. There should be no phase changes or microbial contamination on storage, and the emulsion should maintain elegance with respect to odor, color, and consistency. Instabilities of both chemical and physical origins can occur in emulsion formulations. Chemical instabilities, such as the development of rancidity in natural oils due to oxidation by atmospheric oxygen, the depolymerization of macromolecular emulsifiers by hydrolysis, or microbial degradation can be minimized by the addition of suitable antioxidants and preservatives. More general chemical instabilities involving interactions between the drug and emulsion excipients or between the excipients themselves may lead to physical instabilities. If these interactions involve the emulsifying agent, they may destroy its emulsifying properties, causing the emulsion to break. For example, interactions between phenolic preservatives and polyoxyethylene nonionic emulsifiers may lead to loss of emulsifying power as well as poor preservation.

Physical Instability

As emulsions are inherently unstable, they eventually revert to the original state of two separate liquids, that is, will break or crack. In the presence of an emulsifier and other additives, this state is approached via several distinct processes, some of which are reversible such as creaming and flocculation and others irreversible such as coalescence and Ostwald ripening. Phase inversion when an oil-in-water emulsion inverts to form a water-in-oil emulsion or visa versa is a special case of irreversible instability that occurs only under well-defined conditions such as a change in emulsifier solubility due to specific interactions with additives or to a change in temperature (Fig. 3).

Flocculation describes a weak reversible association between emulsion globules separated by thin films of continuous phase. The individual droplets retain their separate identities, but each floccule or cluster of droplets behaves physically as a single unit. The association arises from the interaction of attractive and repulsive forces

between droplets and is reversible in the sense that the original dispersion can generally be regained by mild agitation. Flocculation is generally regarded as a precursor to the irreversible process of coalescence, although sometimes the time scale between flocculation and coalescence can be extended almost indefinitely by the adsorbed emulsifier, giving a kinetically stable emulsion.

Coalescence, where dispersed phase droplets merge to form larger droplets, takes place in two distinct stages. It begins with the drainage of liquid films of continuous phase from between the oil droplets as they approach one another and ends with the rupture of the film when a critical thickness is reached. The approaching droplets may deform as the opposing surfaces distort to either flatten (small droplets) or dimple (larger droplets) under the hydrodynamic pressures generated by viscous flow of the continuous phase.

Coalescence is not the only mechanism by which dispersed phase droplets increase in size. If the emulsion is

polydispersed and there is significant miscibility between the oil and water phases, then Ostwald ripening, where droplet sizes increase due to large droplets growing at the expense of smaller ones, may also occur. This destabilizing process is a result of the Kelvin effect and occurs when small emulsion droplets (less than 1 μm) have higher solubilities (and vapor pressures) than do larger droplets (i.e. the bulk material) and consequently are thermodynamically unstable. To reach the state of equilibrium, molecules from these droplets dissolve and diffuse through the continuous phase to enlarge the larger droplets. As the small droplets lose their oil, they become even smaller, the vapor pressure difference increases, and Ostwald ripening is further enhanced.

Creaming or sedimentation occurs when the dispersed droplets or floccules separate under the influence of gravity to form a layer of more concentrated emulsion, the cream. Generally a creamed emulsion can be restored to its original state by gentle agitation. This process, which

Fig. 3 Schematic representation of the various processes of emulsion breakdown.

inevitably occurs in any dilute emulsion if there is a density difference between the phases as a consequence of Stokes law, should not be confused with flocculation which is due to particle interactions resulting from the balance of attractive and repulsive forces. Most oils are less dense than water so that the oil droplets in o/w emulsions rise to the surface to form an upper layer of cream. In w/o emulsions, the cream results from sedimentation of water droplets and forms the lower layer. According to Stokes Law, the rate of creaming can be minimized by reducing droplet sizes and/or thickening the continuous phase. Adjustment of the densities of the two phases has received little attention.

The destabilization processes are not independent and each may influence or be influenced by the others. For example, the increased droplet sizes after coalescence or Ostwald ripening will enhance the rate of creaming, as will the formation of large floccules which behave as single entities. In practice, creaming, flocculation, and Ostwald ripening may proceed simultaneously or in any order followed by coalescence.

Coalescence and Ostwald ripening are obviously the most serious types of instability as they result in the formation of progressively larger droplets and ultimately lead to phase separation. Creaming and flocculation, on the other hand, are more subtle forms of instability, for although they represent potential steps towards coalescence and breaking due to the close proximity of the droplets, many practical emulsions remain in this state for long periods of time without significant coalescence and can be redispersed simply by shaking the container.

EMULSION STABILIZATION

Emulsifiers stabilize emulsions in a number of different ways, all of which act to prevent or delay the various destabilization processes described previously. The emulsifier may form an interfacial film at the oil–water interface and/or structure (i.e., thicken) the continuous phase. The interfacial film introduces additional repulsive (e.g., electrostatic, steric, or hydrational) forces between droplets to counteract attractive van der Waals forces and inhibit the close approach of droplets. It may also provide a barrier to the coalescence of droplets in close proximity, particularly if the film is close-packed and elastic. Surfactant interfacial films also lower the interfacial tension between oil and water. Although this effect is important during the emulsification process where it facilitates the breakup of droplets, it is not a major factor in maintaining the long-term stability of emulsions. In emulsions that are thickened

by the emulsifier, the interfacial film does not play the dominant role in maintaining stability; rather, it is the structured continuous phase that forms a rheological barrier to prevent the movement and hence the close approach of droplets and also inhibits Ostwald ripening.

Classical (Interfacial) Theories

Classical theories of emulsion stability focus on the manner in which the adsorbed emulsifier film influences the processes of flocculation and coalescence by modifying the forces between dispersed emulsion droplets. They do not consider the possibility of Ostwald ripening or creaming nor the influence that the emulsifier may have on continuous phase rheology. As two droplets approach one another, they experience strong van der Waals forces of attraction, which tend to pull them even closer together. The adsorbed emulsifier stabilizes the system by the introduction of additional repulsive forces (e.g., electrostatic or steric) that counteract the attractive van der Waals forces and prevent the close approach of droplets. Electrostatic effects are particularly important with ionic emulsifiers whereas steric effects dominate with nonionic polymers and surfactants, and in w/o emulsions. The applications of colloid theory to emulsions stabilized by ionic and nonionic surfactants have been reviewed as have more general aspects of the polymeric stabilization of dispersions (4, 31, 32).

The DLVO theory, which was developed independently by Derjaguin and Landau and by Verwey and Overbeek to analyze quantitatively the influence of electrostatic forces on the stability of lyophobic colloidal particles, has been adapted to describe the influence of similar forces on the flocculation and stability of simple model emulsions stabilized by ionic emulsifiers. The charge on the surface of emulsion droplets arises from ionization of the hydrophilic part of the adsorbed surfactant and gives rise to electrical double layers. Theoretical equations, which were originally developed to deal with monodispersed inorganic solids of diameters less than 1 μm , have to be extensively modified when applied to even the simplest of emulsions, because the adsorbed emulsifier is of finite thickness and droplets, unlike solids, can deform and coalesce. Washington (33) has pointed out that in lipid emulsions, an additional repulsive force not considered by the theory due to the solvent at close distances is also important.

The theory states that the forces between droplets can be considered as the sum of an attractive van der Waals part V_A and a repulsive electrostatic part V_R when identical electrical double layers overlap. As the origin of each force is independent of the other, each is evaluated separately, and the total potential of interaction V_T between the two

droplets as a function of their surface-to-surface separation is obtained by summation

$$V_T = V_A + V_R$$

A schematic potential energy of interaction with distance plot is shown in Fig. 4a. It can be seen that a weak attraction occurs at large droplet separations represented by the secondary energy minimum, and a very strong attraction at small droplet separations hence the very deep primary minimum. At intermediate distances, double-layer repulsion dominates and there is

a maximum in the curve. Flocculation occurs in the secondary minimum, where the attractive forces are relatively weak and floccules are easily separated by low energy agitation. Once flocculated, droplets are prevented from approaching closer by the potential energy barrier. If they have sufficient energy to overcome the barrier, the process of coalescence commences as the droplets move closer together. Once in the primary minimum the aggregates formed are separated by only a small distance so that stability against coalescence is determined by the resistance of the interfacial film to rupture.

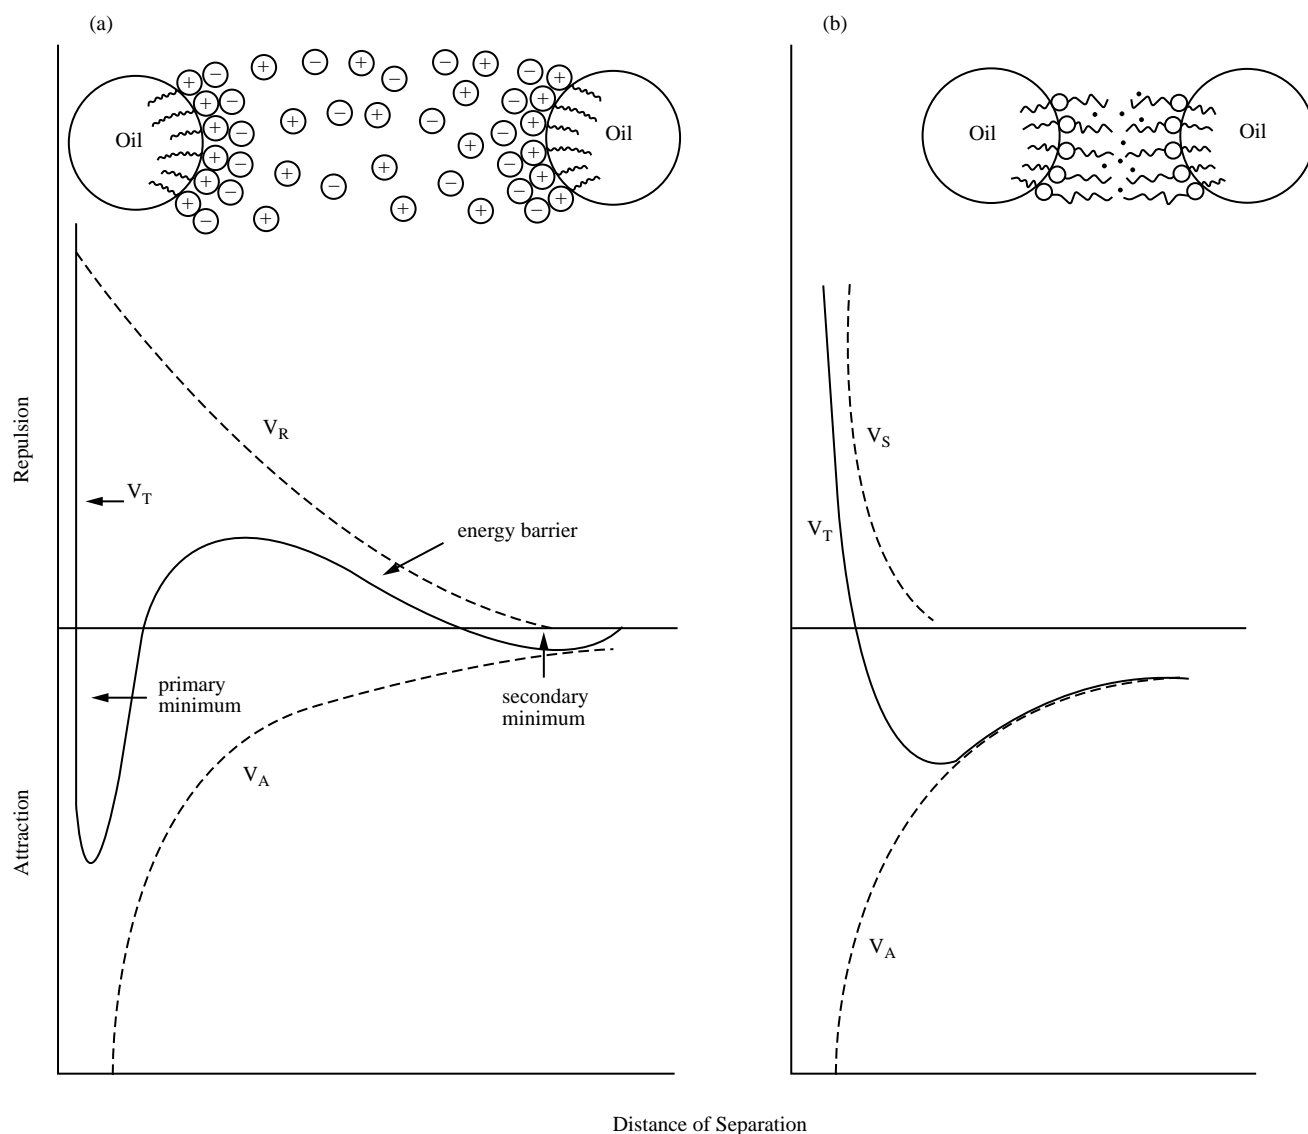

Fig. 4 The total potential energy of interaction V_T as a function of distance of surface separation H for two similar oil droplets in an oil-in-water emulsion. (a) Electrostatic stabilization by a monolayer of ionic surfactant. (b) Steric stabilization by a monolayer of nonionic surfactant. V_A : van der Waals attractive force; V_R : electrostatic repulsive force; V_S : steric repulsive force.

The height of the energy barrier, which is crucial to emulsion stabilization, depends on the state of ionization of the emulsifying agent. Most surfactants are used at pH values where they are totally ionized so that the surface potential is high, giving a correspondingly high energy barrier. The surface potential cannot be measured directly, but can be estimated from the experimentally derived zeta potential. In lipid emulsions for parenteral nutrition, the electrostatic barrier is provided by the ionization of the negatively charged phospholipids in the emulsifier film at the oil droplet–water interface. At physiological pH, a typical fat emulsion carries a negative charge with the zeta potential between 30 and 60 mV. This is sufficient to ensure stability because of the high potential energy barrier. The addition of electrolytes or a change in pH can have a devastating effect on emulsion stability by compressing the double layers, thus reducing the zeta potential and energy barrier and allowing droplets to move into the primary minimum. Thus, great care must be exercised when electrolytes are added nutritional emulsions. With emulsifiers such as proteins and gums, ionization, and hence emulsifying activity, is also pH dependent (c.f. Table 3).

The DLVO theory does not explain either the stability of water-in-oil emulsions or the stability of oil-in-water emulsions stabilized by adsorbed nonionic surfactants and polymers where the electrical contributions are often of secondary importance. In these, steric and hydrational forces, which arise from the loss of entropy when adsorbed polymer layers or hydrated chains of nonionic polyether surfactant intermingle on close approach of two similar droplets, are more important (Fig. 4b). In emulsions stabilized by polyether surfactants, these interactions assume importance at very close distances of approach and are influenced markedly by temperature and degree of hydration of the polyoxyethylene chains. With block copolymers of the ethylene oxide–propylene oxide type, such as the poloxamers, the hydrated polyoxyethylene chains extend into the continuous phase to provide steric stabilization and the hydrophobic propylene oxide portion is anchored onto the droplet surface to form a strong protecting layer against coalescence. Stability is optimized when the droplet surfaces are completely coated by polymer chains so that desorption and lateral movement of the polymer is inhibited. With w/o emulsions, steric hindrance of the adsorbed chains of emulsifier can also result in entropic repulsion effects at small distances of separation.

Some natural polymeric emulsifiers such as the gums, in addition to forming steric and electrostatic barriers form thick multilayered films that are very resistant to film rupture. They may also thicken the continuous phases

of o/w emulsions, thereby reducing the rate of film drainage in the initial stages of coalescence. Small solid particles may stabilize emulsions if they are wetted by both phases and possess sufficient adhesion for one another to form a coherent interfacial film. The film serves as a mechanical barrier to prevent the coalescence of droplets, and if charged, electrostatic mechanisms further assist in the stabilization of the emulsion. Although solids are not generally sufficient to stabilize emulsions on their own, they often reinforce the effectiveness of other emulsifiers.

Stabilization by Mixtures of Emulsifiers

Most pharmaceutical emulsions, whether dilute mobile systems for internal use or thick semisolid creams for application to the skin, contain mixtures of emulsifiers, as these provide more stable preparations. For example, traditional oral preparations are sometimes stabilized by mixtures of gums such as acacia and tragacanth and mixtures of nonionic surfactants of high and low hydrophile–lipophile balance (HLB) generally form more stable emulsions than a single surfactant. The lecithins used to stabilize parenteral emulsions are usually mixtures of neutral and charged lipids as are the partially neutralized glyceryl esters such as self-emulsifying glyceryl monostearate. Combinations of sparingly soluble long-chain acids, alcohols, or glyceryl esters with more soluble ionic and non-ionic surfactants are widely used in dermatological o/w lotions and creams, where they are sometimes added in the form of a preblended emulsifying wax (Table 4). Surfactant/fatty acid combinations are also present in traditional liniment and lotion emulsion formulations prepared by the nascent soap method and in preparations where triethanolamine soaps are formed *in situ* from the interaction of triethanolamine and excess fatty acid.

Equations from the DLVO theory even if modified to allow for the steric repulsive forces cannot cope with mixtures of emulsifiers. Increased stability in model emulsions (c.f. Fig. 1a) is attributed not so much to the control of flocculation (although this does occur), but rather to the prevention or retardation of coalescence by closer packing of the molecules in the adsorbed monolayer to form a more rigid and condensed film. There is now substantial evidence that interactions between emulsifier components to form specific lamellar phases, either liquid crystalline or gel, that are capable of incorporating large volumes of water are important for the stability of many parenteral and dermatological emulsions. Mobile parenteral injections stabilized by

Table 4 Typical emulsifying waxes and their component surfactants

Emulsifying wax	Components
Emulsifying wax USNF	Cetearyl alcohol, polysorbate
Cationic emulsifying wax BP	Cetearyl alcohol, cetrimonium bromide
Cetomacrogol emulsifying wax BP	Cetearyl alcohol, ceteth 20
Glyceryl stearate, SE	Glyceryl stearate, soap

phospholipid mixtures usually contain swollen lamellar liquid crystals (34) whereas a swollen gel phase which generally provides better stability as well as a means of controlling rheological properties dominates in semisolid dermatological emulsions prepared with emulsifying waxes. The relevance of bilayer gel and liquid crystalline phases in dermatological and parenteral emulsions have been discussed in reviews (10, 29). Much of the information about their structures was obtained from investigations of the phase behaviour of emulsifiers and their components in water over the ranges of concentration and temperature relevant to the manufacture, storage, and use of the formulations. It is interesting to note that the same electrostatic, hydration, and steric forces that operate in simple emulsions also dominate the stability and properties of the lamellar phases (35).

Ostwald Ripening

Ostwald ripening has not been studied as extensively in emulsions as has coalescence, although it is a major mechanism for instability in lipid and perfluorochemical emulsions with submicron droplet sizes where a condensed monolayer is not always necessary for emulsion stability (36). Although surfactant interfacial films protect against flocculation and coalescence, Ostwald ripening may in fact be enhanced if the surfactant is above the critical micelle concentration (cmc) because of the diffusion of solubilized oil through the continuous phase. The addition of a third component to the emulsion that has a lower vapor pressure and solubility than the disperse phase will also inhibit Ostwald ripening. The addition of long-chain alkanes to comparatively unstable oil-in-water emulsions prepared with sodium dodecyl sulfate resulted in marked increases in stability even though the alkanes do not effect the composition or mechanical properties of the oil–water interface (37). The stability of pure perfluorodecalin emulsions used as blood substitutes is enhanced by the addition of a small quantity of perfluorotributylamine, and lipid emulsions containing local anaesthetic/analgesic drugs show enhanced stability

in the presence of hydrophobic excipients of lower solubility than the disperse phase (38). Polymeric emulsifiers possibly stabilize emulsions against Ostwald ripening by increasing the viscosity of the continuous phase. The relative lack of Ostwald ripening in emulsions prepared from oils immiscible with water, such as mineral oil, may partly explain why they are easier to emulsify than are more miscible vegetable oils used in parenteral preparations.

Selection of Emulsifier

Over the years there have been many attempts to find systemic methods for screening potential emulsifiers from the enormous number of surfactants available commercially. Although the mechanisms governing the stability of emulsions, including the complex multiple phase systems of pharmacy are becoming clearer, there are still few scientific guidelines to assist in the proper selection of emulsifiers for a particular emulsion. Semiempirical methods based on both interfacial considerations and the phase behavior of the emulsifiers are considered briefly next.

The hydrophile–lipophile balance (HLB) concept

Griffin devised the concept of hydrophile–lipophile balance (HLB) and its additivity many years ago for selection of nonionic emulsifiers and this rather empirical method is still widely used. The enormous literature on the HLB of surfactants has been reviewed by Becher (39). Each surfactant is allocated an HLB number usually on a scale of 0–20, based on the relative proportions of the hydrophilic and hydrophobic part of a molecule. Water-in-oil emulsions are formed generally from oil-soluble surfactants of low HLB number and oil-in-water emulsions from more hydrophilic surfactants of high HLB number. The method of selection is based on the observation that each type of oil will require an emulsifying agent of a specific HLB number to produce a stable emulsion. Thus, oils are often designated two “required” HLB numbers, one low and one high, for their emulsification to form water-in-oil and oil-in-water

emulsions respectively. A series of emulsifiers and their blends with HLB values close to the required HLB of the oil are then examined to see which one forms the most stable emulsion (c.f. Fig. 1a).

Although the HLB concept narrows the range of emulsifiers to select and provides a schematic approach for the formulator, it is limited by its strict relation to molecular structure of the individual surfactants. The concept does not consider the total emulsion and is therefore insensitive to interactions between emulsifier components, the influence of temperature changes, or the presence of additional ingredients in the emulsion. Consequently, not all emulsifier blends of the correct HLB form stable systems. For example, when surfactants of widely different HLB numbers are blended to give the optimum theoretical HLB, the high solubility of the surfactant in the oil and aqueous phases change the balance of the molecules at the interface and unstable emulsions may result. Similarly, if the added surfactants form intermolecular associations at the interface, the association complex is unlikely to have properties that are related in any simple way to the individual properties of the constituent molecules.

The phase inversion temperature (PIT) method (HLB-temperature)

A complementary means of emulsifier selection, the phase inversion temperature (PIT), which employs a characteristic property of the emulsion rather than the properties of the emulsifiers in isolation, was introduced by Shinoda (40). The method uses the fact that the stabilities of oil-in-water emulsions containing nonionic surfactants are closely related to the degree of hydration of the interfacial films. Emulsion stability is reduced by increase in temperature or added salts because these decrease the extent of interfacial film hydration. Phase inversion, due to a change from preferential water solubility of the emulsifier film at low temperature to preferential oil solubility at high temperature, will occur at a specific temperature unique to the particular emulsion and this can be determined experimentally. As a general rule, relatively stable oil-in-water emulsions are obtained when their temperatures during storage and use are between 20 and 65°C below the PIT, presumably because the films are sufficiently hydrated. Mixtures of emulsifiers with identical HLBs produce emulsions with quite different PITs because additives and interactions between the components affect PIT but not HLB.

Microscopic selection for multiple phase emulsions

The better understanding of the mechanisms of stability in complex dermatological emulsions stabilized by

surfactants and amphiphiles has enabled the development of a rapid microscopic method for evaluation of potential emulsifiers. The method is based on the observation that good emulsifier blends that stabilize emulsions by the formation of multilayers of stable gel phase also swell spontaneously in water at ambient temperature and this process can be observed microscopically. Mixtures that do not form gel phase or form metastable gels only after a heating and cooling cycle cannot be observed to swell spontaneously at ambient temperature (4).

Emulsification Techniques

Emulsions are usually prepared by the application of mechanical energy produced by a wide range of agitation techniques. These disrupt droplets by the application of either shear forces in laminar flow or inertial forces in turbulent flow. Emulsifying devices ranging from simple hand mixers and stirrers to the use of propeller or turbine mixers, static mixers, colloid mills, homogenizers, and ultrasonic devices have been used.

Emulsifiers also have an important role in the process of emulsification. Surfactant emulsifiers reduce interfacial tensions during emulsification, making droplets easier to break up as well as reducing the tendency for recombination. Other emulsifiers such as the polymer macromolecules alter the hydrodynamic forces during the agitation process by their influence on rheological properties. Scale-up procedures from the laboratory to manufacture can introduce a number of problems due to the difficulties in matching the exact conditions of mixing, and, because of entrapment-of air, especially in emulsions of high consistency that have a yield value. Along with being inelegant, even traces of atmospheric air can cause decomposition in drugs or excipients susceptible to oxidation.

There are additional constraints when manufacturing parenteral emulsions that must be sterile and of fine particle size. Perfluorochemical and fat emulsions are usually prepared by homogenization at high temperature and pressure, as a large output of energy is required to produce droplet sizes considerably less than 1 μm . Although heat sterilization is widely used, this places a severe test on the stability, and emulsions are sometimes prepared from sterile components under strict aseptic conditions and further sterilized by filtration (15).

Processing variables

Differences in manufacturing techniques such as the rate of the heating and cooling cycle, the extent and order of mixing can cause variations in the consistency and

rheology of the resulting emulsions. The initial particle size of the emulsion depends on the emulsifiers used, the emulsification equipment, the addition speed, and the phase volume. If the surfactant is placed in one of the phases prior to emulsification, it will migrate to the other to establish equilibrium. Thus, emulsification temperatures and cooling rates are important and the time of the mixing should be sufficient to allow the surfactant to migrate to and equilibrate at the interface throughout the process. Oil-in-water emulsions are sometimes prepared by the phase inversion technique, where the aqueous phase is added to the oil phase to form a w/o emulsion that inverts to an o/w emulsion on addition of further amounts of water. This process is claimed to give finer emulsions.

Preparation techniques, in particular cooling rates and mixing procedures, have a marked effect on initial and final consistencies of emulsions prepared with nonionic emulsifying waxes. For example, "shock" cooling and limited mixing initially produces very mobile systems whereas slow cooling with adequate mixing produces semisolid emulsions. Mixing time, when the emulsifiers are in the molten state, influences the distribution of surfactant within the molten masses and bilayers and the relative lamellar order within the system. With ionic emulsifying waxes, different preparation techniques cause comparatively minor variations in the consistency of the final product. It was shown that differences are not due to the gel phase component of cationic ternary systems, but rather due to the variations in size of the crystalline alcohol that precipitates after manufacture. Systems formed by a rapid "shock" cooling method exhibited smaller but greater numbers of cetostearyl alcohol crystals and were thicker than similar ternary systems manufactured by a more lengthy procedure (29).

MICROEMULSIONS

Microemulsions are thermodynamically stable, transparent (or translucent) dispersions of oil and water that are stabilized by an interfacial film of surfactant molecules. The surfactant may be pure, a mixture, or combined with a cosurfactant such as a medium-chain alcohol (e.g., butanol, pentanol). These homogeneous systems, which can be prepared over a wide range of surfactant concentrations and oil to water ratios (20–80%), are all fluids of low viscosity.

The term microemulsion, which implies a close relationship to ordinary emulsions, is misleading because the microemulsion state embraces a number of different microstructures, most of which have little in common

with ordinary emulsions. Although microemulsions may be composed of dispersed droplets of either oil or water, it is now accepted that they are essentially stable, single-phase swollen micellar solutions rather than unstable two-phase dispersions. Microemulsions are readily distinguished from normal emulsions by their transparency, their low viscosity, and more fundamentally their thermodynamic stability and ability to form spontaneously. The dividing line, however, between the size of a swollen micelle (~10–140 nm) and a fine emulsion droplet (~100–600 nm) is not well defined, although microemulsions are very labile systems and a microemulsion droplet may disappear within a fraction of a second whilst another droplet forms spontaneously elsewhere in the system. In contrast, ordinary emulsion droplets, however small, exist as individual entities until coalescence or Ostwald ripening occurs.

Figure 5 shows a hypothetical phase diagram with representation of microemulsion structures. At high water concentrations, microemulsions consist of small oil droplets dispersed in water (o/w microemulsion), while at lower water concentrations the situation is reversed and the system consists of water droplets dispersed in oil (w/o microemulsions). In each phase, the oil and water droplets are separated by a surfactant-rich film. In systems containing comparable amounts of oil and water, equilibrium bicontinuous structures in which the oil and the water domains interpenetrate in a more complicated manner are formed. In this region, infinite curved channels of both the oil and the water domains extend over macroscopic distances and the surfactant forms an interface of rapidly fluctuating curvature, but in which the net curvature is near zero.

Pharmaceutical and Biological Applications of Microemulsions

Microemulsions provide ultralow interfacial tensions and large interfacial areas as well as the ability to concentrate and localize significant amounts of both oil- and water-soluble materials within the same isotropic medium. Over the years, attention has been focused on their potential use as novel reaction media for a wide range of chemical, biochemical, and photochemical reactions, and as carriers for chemicals and small particles, reviewed by Eccleston (41). Inverse microemulsions of the w/o type are the subject of particular interest because of the rapidly emerging range of biotechnological applications based on their ability to solubilize enzymes in the water domains without denaturation or loss of activity. The ability of such solubilized hydrophilic enzymes to transform hydrophobic substrates dissolved in the organic

Fig. 5 Ternary phase diagram for oil, water, and surfactant mixtures showing micellar, microemulsion, and multiphase macroemulsion regions with schematic representations of various structures.

phase could lead eventually to the synthesis of new drugs. As with ordinary emulsions, microemulsions show improved gastrointestinal absorption. They also have a number of other advantages over macroemulsions for drug delivery. Microemulsions form spontaneously without the aid of high shear equipment or significant heat input (heat and gentle mixing are required only if it is necessary to melt any of the ingredients) and their microstructures are independent of the order of addition of the excipients. Optical transparency and low viscosity of microemulsions ensure that they are cosmetically elegant and easy to handle and pack, and their indefinite stabilities ensure a long shelf life. Microemulsions have thus attracted much interest in their drug delivery potential. Both o/w and w/o emulsions have been shown to enhance the oral bioavailability of drugs, including various peptides (42). A peroral concentrate of cyclosporine is now available commercially (Sandimmune Neoral[®] Novartis), which forms a microemulsion

in the aqueous fluids of the gastrointestinal tract. In this preparation, the rate of absorption of cyclosporin is more rapid and less variable than it is with the conventional oily dispersion. Calcein administered intraduodenally in the aqueous phase of a w/o microemulsion prepared from medium-chain triglycerides (43) produces significantly higher plasma levels of the drug compared with an aqueous solution.

Microemulsions have also been used for topical delivery where they increase drug absorption. For example, cetyl alcohol, which is commonly used as an emulsifier in lotions and creams, is absorbed faster and deeper into the skin when formulated as a component of a microemulsion (44). Although efficient skin penetration may be desirable for a therapeutic agent, the relatively high concentrations of surfactant (10–25%) and cosurfactant or cosolvent (5–10%) in such formulations could enhance skin absorption of potential irritants or carcinogens. In fact, the main limitations in realizing

the full potential of microemulsions as drug delivery systems are the narrow range of surfactants, cosurfactants, solvents, and other materials acceptable pharmaceutically.

Microemulsion Formation

Many approaches have been used to explore the mechanisms of microemulsion formation and stability [summarized by Eccleston (41) and Attwood (45)]. Early theories considered interfacial aspects of microemulsions and did not distinguish between thermodynamically stable systems and very fine kinetically stable emulsions. For microemulsions to form spontaneously, the free energy involved when the interfacial area is increased, ΔG ($\Delta G = \gamma \Delta A$, where ΔA is the increase in interfacial area) must be negative. An essential requirement is that the interfacial tension between the oil and water phases γ , is reduced to a very low value by the interfacial film, giving a small but positive free-energy value. The dispersion of the droplets in the continuous phase increases the entropy of the system. Microemulsions form because the negative free energy changes due to the entropy of the dispersion of droplets in the continuous phase overcomes the positive product of the small interfacial tension and the large interfacial area A .

The curvature of the oil–water interface in microemulsions varies from highly curved towards oil (o/w) or water (w/o) to zero mean curvature in bicontinuous structures. The type of microemulsion that forms depends on the properties of the surfactant, cosurfactant and the oil. Although there are no strict rules for choosing the appropriate microemulsion components, there are a number of general guidelines based on empirical observations. The surfactant(s) chosen for a particular oil must:

1. lower interfacial tension to a very low value to aid dispersion processes during the preparation of the microemulsion.
2. be of the appropriate hydrophile-lipophile character to provide the correct curvature at the interfacial region for the desired microemulsion type, o/w, w/o or bicontinuous.
3. provide a flexible film that can readily deform round small droplets.

The analysis of film curvature for surfactant associations leading to microemulsion formation has been rationalized by Mitchell and Ninham. They used a packing ratio P defined as V/al , where V is the partial molar volume of the surfactant, a the cross sectional area (i.e. size) of the surfactant head group, and l the maximum length of the surfactant chain (46). The packing ratio provides a direct measure of HLB and is influenced by the same factors. Oil-in-water microemulsions are favored if the effective polar part of the surfactant is more bulky than the hydrophobic part, that is, P varies from 0 to 1, and the interface curves spontaneously towards water (positive curvature). Water-in-oil microemulsions form when the interface curves in the opposite direction, that is, P is greater than 1 (negative curvature). At zero curvature, when the HLB is balanced and P is zero, either bicontinuous or lamellar structures may form according to the rigidity of the film. The critical packing parameter P is based purely on geometric considerations. Hydration of the surfactant head group and penetration of the oil and the cosurfactant into the surfactant film also affect the packing and curvature, as summarized in Table 5, which also illustrates how formulation variables may be manipulated to produce a microemulsion of the desired type (47).

Most single-chain surfactants do not lower the oil–water interfacial tension sufficiently to form microemulsions nor are they of the correct molecular structure, and

Table 5 Factors affecting spontaneous curvature of monolayers

Variable	Curvature effect	Cause
Increase oil chain length	More positive	Less penetration of surfactant tail region
Addition of shorter chain cosurfactant	More positive	Alcohol swells head region more than tail region
Addition of longer chain cosurfactant	More negative	Alcohol swells surfactant chain region more than head region
Addition of salt (ionic surfactant)	More negative	Screened repulsion between polar head groups
Addition of salt (nonionic surfactant)	More negative	Headgroup size reduced by dehydration
Branched or double chained surfactant	More negative	Increased tail group area
Reduced surfactant head group size	More negative	
Increased temperature (nonionic surfactant)	More negative	Headgroup size reduced by dehydration
Increased temperature (ionic surfactant)	More positive	Increased surfactant counter-ion dissociation

(Adapted from Ref. 47.)

short- to medium-chain length alcohols are necessary as cosurfactants. The cosurfactant also ensures that the interfacial film is flexible enough to deform readily around each droplet as their intercalation between the primary surfactant molecules decreases both the polar head group interactions and the hydrocarbon chain interactions. Medium-chain alcohols such as pentanol and hexanol have been used by many investigators as they are particularly effective cosurfactants. They are not, however, suitable for pharmaceuticals due to their high irritant potential. Double-chain surfactants such as anionic Aerosol-OT (bis-2-ethylhexyl sulfosuccinate) or cationic DDAB (didodecyltrimethylammonium bromide), which have relatively small head groups and bulky hydrophobic portions, are already of the required HLB to form w/o microemulsions spontaneously without a cosurfactant. Unfortunately, these widely investigated surfactants are too toxic for general pharmaceutical or biotechnological applications. Double-chain phospholipids such as the phosphatidylcholines of lecithin are an obvious possibility. Although lecithin is too lipophilic to form microemulsions, pharmaceutically acceptable microemulsions have been prepared from double-chain phospholipids by using acceptable cosurfactants such as ethanol, propanol, or *n*-butanol with isopropyl myristate (48, 51). Self-emulsifying drug delivery systems are composed of triglyceride oils and surfactant mixtures that undergo spontaneous emulsification when mixed with water (52). This principle is used in the commercial product Sandimmune Neoral[®], which forms a microemulsion in situ when diluted by gastric fluid.

Formulation and Preparation of Microemulsions

As microemulsions are thermodynamically stable, they can be prepared simply by blending oil, water, surfactant, and cosurfactant with mild agitation. Once the appropriate microemulsion components have been selected, quaternary phase diagrams or ternary pseudo-phase diagrams may be constructed to define the extent and nature of the microemulsion regions and the surrounding two- and three-phase domains. The microemulsion region can be identified and characterized using the range of light, neutron, and X-ray scattering and other techniques such as NMR and microscopy (45). Problems arise in interpretation of data in systems of high droplet volume fraction due to interdroplet interactions. The normal practice of investigating systems at relatively low concentrations and then extrapolating to zero concentration in order to eliminate interparticle interactions cannot be applied to

microemulsions as it is not possible to dilute the systems without affecting their structure. Hard sphere models, such as those adapted from Percus and Yevick, have been successfully used to analyze scattering data from concentrated w/o microemulsions (53).

Electrochemical Detection for Pharmaceutical Analysis

Damon M. Osbourn

Craig E. Lunte

The University of Kansas, Lawrence, Kansas, U.S.A.

INTRODUCTION

In order to bring a drug product from the discovery stage to the commercial market, many analytical methods must be employed. The analytical chemist develops methodology for quality control, stability testing, pharmacokinetics, identification, and clinical studies. Analysts choose from a number of techniques such as NMR, MS, separations, spectroscopy, and electrochemistry, each with its own advantages. Electrochemistry has many advantages, which make it an appealing choice for pharmaceutical analysis. Most electrochemical techniques have excellent limits of detection and a wide dynamic range. Electroanalytical techniques require only very small sample volumes, often in the microliter range, coupled with the low detection limits allowing analysis on subpicogram amounts of analyte. The selectivity of electrochemical detection in complex samples is excellent because fewer electroactive interferents are often encountered than spectroscopic interferents. For these reasons, electrochemistry is uniquely suited for clinical and bioanalysis, where small volumes of blood or urine are analyzed for low concentrations of drug products and metabolites. Additionally, many methods for *in vivo* analysis have been developed. Finally, in comparison to other analytical techniques, the instrumentation required for electrochemical methods is simple and inexpensive, even to the point of having disposable electrochemical cells. With the advent of micromachining technologies, the designs of electrochemical cells promise to become even more reproducible, simple, and inexpensive.

Electrochemical detection is based on the electrical signal arising between two electrodes immersed in a sample solution. Electroanalytical techniques fall into two main categories, potentiometric and Faradaic techniques. Potentiometry is the measurement of a potential difference between two electrodes under equilibrium conditions (i.e., no current flow). The potential is then related to concentration of the analyte species. Faradaic processes are based on the oxidation or reduction of the analyte, where a specific potential waveform is applied and the current is used to extract information about the sample. Many different techniques have been developed to gain

quantitative and qualitative information about analytes of interest. This article covers the basics of many different techniques useful in pharmaceutical analysis and directs the reader to current pharmaceutical applications in the literature.

Potentiometric Techniques

Although electrochemistry has the stigma of being difficult to use, and therefore is often overlooked as an analysis option, potentiometric measurements are probably the most common technique encountered. Many analytical chemists make potentiometric measurements daily, whenever they use a pH meter. Potentiometry is based on the measurement of the potential between two electrodes immersed in a test solution. As the electrical potential of the cell is measured with no current flow between the electrodes, potentiometry is an equilibrium technique. The first electrode, the indicator electrode, is chosen to respond to the activity of a specific species in the test solution. The second electrode is a reference of known and fixed potential. The design of the indicator electrode is fundamental to potentiometric measurements, and should interact selectively with the analyte of interest so that other sample constituents do not interfere with the measurement. Many different strategies have been developed to make indicator electrodes that respond selectively to a number of species including organic ions.

An example of an electrochemical cell for potentiometry is shown schematically in Fig. 1. The cell consists of an external reference electrode and an indicator electrode immersed in a test solution of analyte with some activity, $(a_i)_{\text{sample}}$. The indicator electrode is constructed of a reference electrode contained within a membrane and an internal reference electrolyte of fixed activity, $(a_i)_{\text{internal}}$. The potential (E_{cell}) is measured by a pH/mV meter, and is equal to the sum of the potential between the internal ($E_{\text{ref,int}}$) and external ($E_{\text{ref,ext}}$) reference electrodes, the membrane potential (E_{memb}), plus the liquid junction potential (E_{lj}) that exists at the junction between the external reference electrode and the sample solution.

Fig. 1 General schematic of a potentiometric electrochemical cell.

$$E_{\text{cell}} = E_{\text{ref,int}} - E_{\text{ref,ext}} + E_{\text{memb}} + E_{\text{lj}} \quad (1)$$

If the semipermeable membrane is selective for a particular ion (i), a potential gradient will develop across the membrane. The gradient, described by the Nernst equation, depends on the ratio of the activity of the ion on either side of the membrane:

$$E_{\text{memb}} = \frac{RT}{zF} \ln \frac{(a_i)_{\text{sample}}}{(a_i)_{\text{internal}}} \quad (2)$$

where z is the charge on the ion, R is the gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), T is the temperature (K), and F is the Faraday ($96,485 \text{ C mol}^{-1}$). By the substitution of Eq. 2 into Eq. 1, an overall expression for the electrochemical cell can be written as follows:

$$E_{\text{cell}} = E_{\text{ref,int}} - E_{\text{ref,ext}} + \frac{RT}{zF} \ln \frac{1}{(a_i)_{\text{internal}}} + E_{\text{lj}} + \frac{RT}{zF} \ln(a_i)_{\text{sample}} \quad (3)$$

The potentiometric cell is constructed so that the half-cell potentials of the two reference electrodes and the composition of the internal electrolyte are constant. The sample solution is maintained at a high constant ionic strength so that E_{lj} is effectively constant. This allows Eq. 3 to be simplified to yield:

$$E_{\text{cell}} = K + \frac{0.0591}{z} \log(a_i)_{\text{sample}} \quad (4)$$

when the temperature is 25°C , and K represents the terms which are constant in Eq. 3. This relationship between cell potential and analyte activity is the basis of potentiometry. A plot of E_{cell} vs. $\log a_i$ for a series of analyte concentrations

should be linear with a slope of $0.0591/z$ for measurements made at 25°C .

Unfortunately, membranes respond to some extent to ions in solution other than the analyte. A more general expression than Eq. 4 is:

$$E_{\text{cell}} = K + \frac{0.0591}{z} \log(a_i + k_{ij}a_j^{z/x}) \quad (5)$$

where a_j is the activity of the interfering ion j , x is the charge of ion j , and k_{ij} is the selectivity constant of the measurement. Small values of k_{ij} are characteristic of electrodes with good selectivity for the analyte i .

Faradaic Techniques

Faradaic techniques are those in which oxidation or reduction of analyte species occurs at the electrodes and therefore a measurable current is passed through the electrochemical cell. This discussion will be limited to controlled-potential techniques, primarily voltammetry and amperometry, coupled to liquid chromatography. While other Faradaic electrochemical techniques have been developed and electrochemical techniques in bulk solution are common, the use of liquid chromatography employing these two detection strategies is by far the most common electroanalytical technique in pharmaceutical studies.

Application of some potential waveform to an electrode in contact with the sample solution is the basis of all controlled-potential electrochemical techniques. The different techniques simply manipulate the monitored output by either varying the applied potential waveform or by changing the response domain. This response can be current, charge, or in some cases photons. An advantage of electrochemical techniques is that the instrumental requirements are rather simple and essentially the same for all techniques. A basic system consists of a potentiostat for potential control of an electrode and a means of detecting a response (usually the current through the electrode). Indeed, single instruments capable of performing many electrochemical techniques are available from several sources.

For successful application of Faradaic electrochemical techniques, it is necessary to understand the fundamental processes that occur at the surface of the electrode in electrolyte solution. When a potential is applied between two electrodes in solution, a narrow interphase region, the electrical double-layer, develops at the surface of the electrodes. All oxidative or reductive electrochemical reactions between the electrode and the analyte occur in this interphase region between the electrode surface and bulk solution. The bulk solution will remain at electro-neutrality because the potential drop between the electrodes only exists in the interphase region. Therefore,

molecules in the bulk solution cannot feel the presence of the electrodes or the potential gradient. Only molecules within the electrical double-layer (typically less than 10^{-6} m from the electrode) are probed during an electrochemical experiment.

It is equally important to understand how the electrode is experimentally set at some potential relative to the bulk solution. The potential difference between the electrode and the bulk solution cannot be measured; therefore, it is necessary to use a second electrode. Because the potential difference between two electrodes in solution can be determined, if the solution electrode potential difference of one of the electrodes is held constant, then the potential difference between the solution and the second electrode can be directly related to the potential difference between the two electrodes. The potential between one electrode and the solution is held constant by employing a reference electrode. The reference electrode uses a reversible redox couple such as silver–silver chloride to maintain a constant potential of fixed reference value. The potential between the bulk solution and the electrode is established relative to this reference point, even though it is not known in an absolute sense.

In the two-electrode system described before, the electrode of reference potential is known as the counter electrode while the electrode at which the potential difference is applied relative to the counter electrode is termed the working electrode. It is at the working electrode where the redox process of interest occurs. In addition to maintaining a reference potential, the counter electrode serves the second purpose of completing the electrical circuit and allowing charge to pass through the cell. Unfortunately, the two functions of the counter electrode are not independent of one another. When a current is passed through the counter electrode, a change in its potential difference with the solution can arise. This effect appears at even low currents and in most designs the problem is circumvented by splitting the counter electrode into two electrodes to give an overall three-electrode system. In the three-electrode system, the reference electrode maintains the constant reference potential, the electrode used to complete the electrical circuit is termed the auxiliary electrode, and the electrode at which the potential is applied to drive redox reactions is known as the working electrode (Fig. 2). In this arrangement there is negligible current through the reference electrode so its potential relative to the solution is constant regardless of the current through the electrochemical cell (working to auxiliary electrode).

In a high dielectric medium like water, when a potential is applied between an electrode and the solution, charge excess will develop on the electrode surface and the

Fig. 2 General schematic of a Faradaic electrochemical cell.

amount of charge will be proportional to the applied potential. Solvent molecules and electrolyte species orient themselves at the electrode surface to counter the electrode charge. This is the interphase region, and is known as the double-layer because of the theoretical arrangement of molecules. This electrode–solution interface behaves in a manner similar to a capacitor. “Double-layer charging currents” are thus produced when the potential difference between the electrode surface and the solution is changed. These charging currents have little consequence in constant potential techniques such as amperometry; however, they can have a significant effect on voltammetric techniques, which will be discussed later.

Faraday’s law is the basis of all electroanalytical chemistry:

$$Q = nFN \quad (6)$$

where Q is the charge (C), n is the number of electrons transferred (equiv. mol^{-1}), F is the Faraday constant ($96,485 \text{ C equiv.}^{-1}$), and N is the number of moles of reactant. Faraday’s law shows the direct relationship between the charge passed through an electrochemical cell and the quantity of chemical reaction that has taken place. For analytical purposes, it is often more useful to take the derivative of Faraday’s law with respect to time:

$$i(t) = (dQ/dt) = nF(dN/dt) \quad (7)$$

where $i(t)$ is the current (A) as a function of time and dN/dt is the rate of conversion of reactant at the electrode surface. In this form, Faraday’s law becomes a rate equation relating the rate of a chemical reaction to an electrical response. Electrochemistry is one of the few techniques that make instantaneous, single point rate measurements. The equations describing the responses for the various electrochemical techniques are all based upon this equation.

Consideration of Faraday's law shows the advantage of electrochemistry for analytical purposes. With currents as small as 10^{-9} A, which are easily measured, conversion rates of as little as 10^{-14} equiv. sec^{-1} are readily detectable. This means detection limits in the range of 10^{-9} M can be achieved by electroanalytical techniques.

While electroanalytical techniques are inherently quite sensitive, the resolution of a mixture of electroactive compounds is quite difficult. Practical considerations limit the usable "potential window" to not more than 3 V and typically around 1.5 V. This is because at more extreme potentials, the medium or the electrode itself begins to oxidize or reduce. In addition, the electrochemical response of compounds as a function of applied potential is fairly broad so that at least a 200 mV–400 mV difference in half-wave potentials is required for adequate resolution. This typically limits electrochemical resolution of mixtures to not more than three or four electroactive compounds.

Because of this lack of resolving power, much electroanalytical research is aimed at providing increased selectivity. This can be accomplished in two ways. First, electrochemistry can be combined with another technique, which provides the selectivity. Examples of this approach are liquid chromatography with electrochemical detection and electrochemical enzyme immunoassay. The second approach is to modify the electrochemical reaction at the electrode to enhance selectivity. This approach is exemplified by modified electrode methods where reaction at the electrode surface is limited beyond mere electrochemical considerations to include physical and chemical properties. The following discussion will illustrate in detail how these approaches can provide analytical techniques with both high selectivity and low detection limits.

ION-SELECTIVE ELECTRODES (ISEs)

The ISE has become key in the application of potentiometric applications. In essence, the ISE measures the potential difference across a membrane, and follows the form shown in Fig. 1. Therefore, the measured cell potential, i.e., the electrochemical response, is based on the interaction between the membrane and the analyte that alters the potential across the membrane. The selectivity of the ISE to the analyte depends on the specificity of the membrane interaction with the analyte.

The development of membranes that exhibit both sensitivity and selectivity for species of interest is paramount in the application of ISEs. Between these two properties, selectivity is by far the more difficult one to

achieve. Three basic types of membranes have been developed, because of their selectivity, for ISEs. These are liquid and polymer, solid state, and glass membranes. Electrodes are commercially available for numerous inorganic ions such as H^+ , Li^+ , Na^+ , K^+ , Ag^+ , Ca^{2+} , Cu^{2+} , Pb^{2+} , Cd^{2+} , F^- , Cl^- , Br^- , I^- , SCN^- , NO_3^- , ClO_4^- , and BF_4^- . Additionally, electrodes have been reported for numerous organic anions and cations.^[1–5]

A number of ISEs for organic ions have found application in pharmaceutical analysis.^[6–8] The use of ISEs ranges from determination of excipients^[9] and formulary impurities^[10,11] in finished products to assay of drug product in pharmacokinetic studies.^[12–14]

Ion-Sensitive Field Effect Transistors (ISFETs)

The ISFET is an electrochemical sensor based on a modification of the metal oxide semiconductor field effect transistor (MOSFET). The metal gate of the MOSFET is replaced by a reference electrode and the gate insulator is exposed to the analyte solution or is coated with an ion-selective membrane^[15] as shown in Fig. 3.

The rest of the device is protected by a suitable encapsulant. Insulators such as SiO_2 , Al_2O_3 , and Ta_2O_5 have surface hydroxyl groups that act as sites for chemical reactions when exposed to an electrolyte solution. The alteration in surface charge resulting from protonation/deprotonation of these surface sites affects the surface potential and results in a relation between the drain current of the ISFET and solution pH. For example, an Al_2O_3 -ISFET exhibits a linear response between amplifier voltage and pH over a range of ca. 2.5–10.5 with a slope of 53 mV/pH.^[15] Additionally, ISFET devices for the determination of lidocaine,^[16] cocaine,^[16] benzalkonium,^[16] salicylic and acetylsalicylic acid,^[17] as well as cholanolic acids^[18] have been reported. The main interest in ISFETs stems from the ease with which inexpensive microelectrodes can be produced. However, the commercial success of these devices has been hindered by problems with encapsulation and stability.

LIQUID CHROMATOGRAPHY/ELECTROCHEMISTRY

Liquid chromatography/electrochemistry (LCEC) has become recognized as a powerful tool for the trace determination of easily oxidizable and reducible compounds. This is because detection of as little as 0.1 pmol of material is readily accomplished with relatively simple

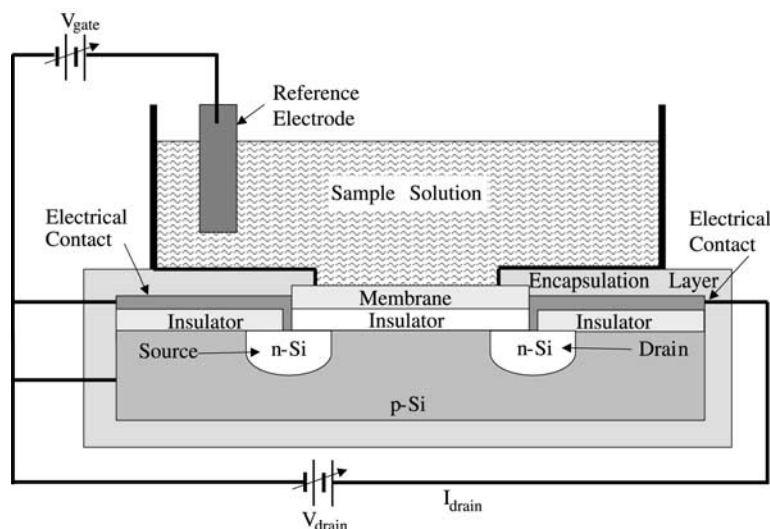

Fig. 3 General schematic of an ISFET.

and inexpensive equipment. Initial interest in LCEC was generated by the determination of several aromatic metabolites of tyrosine in the central nervous system. However, the application of LCEC into other areas of analysis including pharmaceutical analysis and especially pharmacokinetic and pharmacodynamic studies has become common.^[19–22]

Hydrodynamic Voltammetry

The basic characterization of an electrochemical detector for LCEC is the hydrodynamic voltammogram (HDV). Hydrodynamic voltammetry is a steady-state technique in which the electrode potential is altered with successive analyte injections and the current is plotted as a function of the potential. Idealized HDVs for the case of electrolyte solution (mobile phase) alone and with an oxidizable species added are shown in Fig. 4. The HDV of a compound begins at a potential where the compound is not electroactive and therefore no Faradaic current occurs, goes through a region of increasing current, and finally reaches a limiting current plateau, where essentially the entire compound reaching the electrode surface is oxidized. The HDV is characterized by the half-wave potential, $E_{1/2}$, which is defined as the potential at which the current is one-half its limiting value. The slope of the rising portion of the HDV is determined by the Nernst equation and the kinetics of electron transfer at the electrode surface.

The HDV is used to select the operating potential for an LCEC experiment. Two considerations are of major importance. First, quantitative determinations are based on

the extent to which the redox current from the analyte can be distinguished from the background current. Hence, operating at the smallest reasonable applied potential means that the background current typically increases with increasing potential. Second, operating on the limiting current plateau means that the redox current from the analyte is independent of applied potential. Because changes to the electrode surface during the course of an LCEC experiment can cause small changes in the interphase potential difference, operating on the limiting current plateau assures a constant response even if these

Fig. 4 General depiction of an HDV.

small variations occur. Overall, these considerations dictate that a potential just on the limiting current plateau is normally chosen for LCEC experiments.

Mobile Phase Considerations

While all detectors place some limitations on the mobile phase composition, in electrochemical detection, it is essential to recognize that a complex surface reaction is involved, which depends on both the physical and chemical properties of the medium. To optimize an LCEC determination, it is necessary to consider both chromatographic and electrochemical requirements simultaneously. Fortunately, most commonly applied chromatographic techniques fall into the category of reverse phase separations, the mobile phase requirements of which are consistent with the requirements for electrochemistry. The primary requirement for electrochemical detection is that the mobile phase has a relatively high conductivity. To this end, buffered mobile phases of moderate ionic strength (0.01 M–0.1 M) are typically used. Obviously, totally nonpolar organic mobile phases cannot be used because of their inability to support a significant ionic strength. This rules out classical normal phase separations. The vast majority of LCEC applications have employed reverse phase, ion-exchange, or ion-pair separations. While aqueous in nature, significant amounts (up to 90%, v/v) of organic modifier can be added to the mobile phase. Totally nonaqueous mobile phases can be used if the solvent can support an electrolyte. Organic solvents, which have been used with LCEC, include methanol, acetonitrile, DMF, and DMSO with salts such as tetrabutylammonium hexafluorophosphate or tetrafluoroborate as the electrolyte.

Electrode Materials

The choice of the electrode material can be critical to the successful use of LCEC. Historically, the material of choice is carbon paste, a mixture of graphite powder with a dielectric binder such as mineral oil. Carbon paste exhibits low background current at positive potentials and good mechanical stability. However, carbon paste electrodes are incompatible with mobile phases containing more than about 20% organic solvent. As a result, glassy (or vitreous) carbon electrodes have become more popular than carbon paste electrodes. This is primarily because glassy carbon is compatible with organic solvents and is easier to use. In addition, glassy carbon typically exhibits lower background currents at negative potentials than does carbon paste. More recently, diamond electrodes have been

investigated, although they have yet to find widespread appeal. Mercury electrodes have also been employed with LCEC. Because of the poor mechanical stability of mercury alone, it is often amalgamated with gold to form an electrode. Mercury has the best characteristics when operating at negative potentials, but it is generally not applicable to oxidative detection because of the low oxidation potential of mercury itself. Platinum electrodes have been employed to a limited extent, but have found little acceptance due to the problem of surface oxide layer formation. It is impossible to say that one electrode material will be superior to another in all situations. It is best to evaluate each redox system of interest with several types of electrodes to make the optimal choice.

Cell Design

The design of the electrochemical flow cell can dramatically affect the performance of the detector. For this reason, several different cell designs have been devised for chromatographic detection. The most popular design is the thin-layer cell in which the working electrode is part of one wall of a thin-layer channel through which the chromatographic eluent flows. Thin-layer cells can be constructed such that flow is parallel to the electrode^[23] or directed perpendicular to the surface followed by radial dispersion (known as the wall-jet cell)^[24] as shown in Fig. 5. The thin-layer cell design provides a high ratio of electrode surface area to solution volume providing high sensitivity and the excellent flow characteristics of well-developed laminar flow for low flow-related noise. In addition, the thin-layer cell design is compatible with essentially all electrode materials and offers convenient access to the electrode for resurfacing. Most commercially available electrochemical detectors use thin-layer cells.

Flow-through electrochemical detectors based on a cylindrical geometry, as opposed to a planar geometry, have also been developed.^[25–28] Three cell designs using cylindrical geometry have been used with liquid chromatography (Fig. 5). From a practical perspective, open-tubular electrodes are less attractive because many common electrode materials cannot be easily used (e.g., mercury and carbon paste) and resurfacing of electrodes is difficult. The surface-to-volume ratio is also not very large. The wire in a capillary cell design has become more attractive with the advent of open-tubular liquid chromatography columns. Knecht and coworkers^[29] have described the fabrication of such an electrochemical cell directly at the end of an open-tubular chromatographic column.

Packed-bed electrodes (Fig. 5) are useful for constructing electrochemical detectors of high conversion efficiency.

Fig. 5 Flow cells for LCEC: IA) thin-layer cell; IB) wall-jet cell; IIA) open-tubular cell; IIB) wire in a capillary cell; IIC) packed-bed cell.

Because typical packed-bed cells have very large electrode surface areas, high background currents are a problem. Another disadvantage of packed-bed cells is the difficulty of resurfacing the electrode. It is not possible to physically resurface the electrode by polishing and less vigorous chemical methods must suffice. Tubular packed-bed electrode cells are best applicable for electrosynthetic applications where 100% conversion is important.

Most LCEC applications use a single working electrode, although it is possible to monitor the current at several electrodes simultaneously. In practice, this becomes more difficult as more working electrodes are employed so that practical applications have been limited to two working electrodes. Several advantages can be achieved using two working electrodes relative to single-electrode detection.^[30] This configuration, known as a dual-electrode detector, is commercially available in both thin-layer and packed-bed designs.

Both cell designs permit the positioning of the second electrode downstream of the first working electrode (Fig. 6), which is known as the series configuration. This electrochemical transducer is used in the same manner as the classical ring-disk electrode. Products generated at the upstream electrode are detected (or collected) at the downstream electrode.^[31] Selectivity is enhanced when the products of the upstream electrolysis can be detected at a more favorable potential than is necessary for the upstream reaction. In addition, chemically irreversible redox couples

Fig. 6 Dual-electrode cells for LCEC: I) dual-series cells; A) planar; B) cylindrical; IIA) dual-parallel cell; IIB) dual-opposed cell.

are not detected downstream in the series configuration further enhancing selectivity and improving detection limits. This cell design has been applied to the determination of terbutaline in pharmaceutical formulations,^[32] acetaminophen in blood^[33] and urine,^[34] metanephrine and normetanephrine in plasma,^[35] physostigmine and metabolite in blood,^[36] samodil fumarate and metabolite in blood,^[37] oxodipine in plasma,^[38] and roxithromycin in plasma and urine.^[39] The series configuration has also been used to study the electrochemical reactions occurring at the upstream electrode.^[40]

The thin-layer cell design also permits two electrodes to be placed adjacent to each other and normal to the flow path (Fig. 6), which is known as the parallel adjacent configuration. With this configuration, the current at each electrode (typically at different applied potentials) is monitored individually and is analogous to dual-wavelength UV absorption detectors. The parallel configuration can be used in three ways. First, both oxidizable and reducible compounds can be detected simultaneously.^[41] Second, easily oxidizable (or reduced) analytes can be selectively detected in the presence of hard to oxidize (or reduce) analytes by using one electrode at a relatively low potential to detect the easily oxidized analytes and using the other electrode to detect the hard to oxidize analytes at a less selective potential.^[42] This technique was applied to the determination of water-soluble vitamins in pharmaceutical formulations.^[43] Finally, by operating both electrodes at different potentials on the HDV of a compound, voltammetric data can be obtained from a single chromatographic analysis providing qualitative information^[42] as reported for the analysis of Pt-based antineoplastics.^[44]

A third configuration of the dual-electrode thin-layer cell is also shown in Fig. 6. This geometry is known as

the parallel-opposed configuration and provides enhanced response for reversible compounds by redox cycling. As the analyte is cycled from its oxidized to reduced form, many more electrons are transferred than would be with a single working electrode and the current response is thus greatly amplified. Unfortunately, with conventional LC systems, the flow rate through the electrochemical cell is too high to permit a significant number of redox cycles to occur. Goto et al.^[45] have been able to achieve up to a 20-fold increase in response using 1 cm long electrodes spaced 30 μm apart with a flow rate of 20 $\mu\text{L min}^{-1}$ with a microbore chromatography column. With the growing interest in microbore LC and the associated lower volume flow rates, this concept should find more practical application.

While most LCEC experiments directly use the current response at the electrode for quantitation, it is possible to combine the response from two electrodes into a difference response. Many advantages have been described^[46] for LCEC using the series and parallel configurations of the dual-electrode detector in the difference mode. With the parallel configuration, the electrodes are operated at potentials bracketing the region where the current response is most dependent on potential (i.e., $E_{1/2}$). The difference response from the analyte is not significantly different from the response at a single electrode operated at the higher potential. However, the difference response for compounds both harder and easier to oxidize is greatly attenuated. In essence, difference mode detection with parallel configurations establishes a “potential window” through which only compounds whose current response changes can be seen. The major sources of baseline interference in LCEC, such as flow rate and temperature fluctuations, static discharge, and changes in mobile phase composition are common modes (i.e., occur at both electrodes simultaneously). Difference mode detection can be an effective method to improve signal quality because these types of interference signals are greatly attenuated in the difference signal.

With the series configuration, both electrodes are operated at the same potential and on the limiting current plateau of the analyte. Because the diffusion layer is depleted of the analyte at the upstream electrode, the downstream response is greatly attenuated and the difference response is not greatly different than the upstream response alone. However, signal from baseline interferences is greatly attenuated for a large improvement in the signal-to-noise ratio. Because this mode is based on mass transport instead of electrochemistry, no change in selectivity relative to single electrode operation is achieved.

Conversion Efficiency

Depending upon the cell design and flow rate, electrochemical detectors can electrolyze from ca. 5% up to nearly 100% of the material entering the cell. In practice, high efficiency is obtained by using a large surface area electrode. As the electrode surface area is increased, each added increment contributes proportionately less to the total signal, but approximately equal amounts to the background. As background noise is roughly proportional to background current, the signal-to-noise ratio tends to decrease as the electrode area becomes very large. Therefore, although the absolute response of an analyte is larger for high efficiency detectors, limits of detection are typically not better and often worse than for detectors with a conversion efficiency of 10%–20%. A detector of 100% conversion efficiency can be useful for the quantitation of an analyte for which no standard is available. If the number of electrons involved in the electrochemical reaction is known and the chromatographic peak is baseline resolved so that an accurate peak area can be determined, then quantities can be calculated directly from Faraday's law. This is not a very common occurrence in practice.

Voltammetric Detection

To obtain more complete voltammetric information than is readily found with amperometric detection, various potential scanning detectors have been developed for liquid chromatography. Simple use of a linear ramp waveform, such as used in linear sweep and cyclic voltammetry, is not very useful for chromatographic detection. Because the signal current of an analyte is relatively small in LC detectors, double-layer charging currents can easily obscure the voltammetric information. In addition, the cell resistance is typically large in cells used for chromatographic detection causing a significant iR drop that distorts the voltammogram.

To overcome these problems, most voltammetric detectors have used pulsed waveforms such as staircase,^[47] squarewave,^[48] and differential pulse.^[49] The current is sampled at the end of the pulse after the charging current has decayed. In addition, because the charging current is typically the major current source, iR problems are not as severe. Last^[50] has described a coulometric detector based on charge pulses instead of potential pulses, which eliminates iR and charging current problems. Even with these pulse techniques, voltammetric detection methods have not been able to achieve the detection limits readily obtained by simple amperometric detectors. White et al.^[51] have described a voltammetric detector using a fiber

microelectrode that exhibited greatly reduced charging currents. Unfortunately, this detector was limited to use with open-tubular chromatographic systems.

A unique voltammetric detector^[52] has been developed using a series dual-electrode cell. In the detector, the upstream electrode's potential is scanned while the downstream electrode is used to monitor the redox reaction occurring at the upstream electrode without the charging current contributions. In essence, the upstream electrode is operated voltammetrically and the downstream electrode operated amperometrically so that the detector has been named a voltammetric–amperometric detector. Detection limits of 10^{-7} M have been reported using this detection scheme.

ENZYME-LINKED ELECTROCHEMICAL TECHNIQUES

Monitoring enzyme-catalyzed reactions by voltammetry and amperometry is an extremely active area of bioelectrochemical interest. Whereas liquid chromatography provides selectivity, the use of enzymes to generate electroactive products provides specificity to electroanalytical techniques. In essence, enzymes are used as a derivatizing agent to convert a nonelectroactive species into an electroactive species. Alternatively, electrochemistry has been used as a sensitive method to follow enzymatic reactions and to determine enzyme activity. Enzyme-linked immunoassays with electrochemical detection (discussed in “Electrochemical Immunoassay”) have been reported to provide even greater specificity and sensitivity than other enzyme-linked electrochemical techniques.

Enzyme-linked electrochemical techniques can be carried out in two basic ways. The first approach is to use a hydrodynamic technique, such as flow injection analysis (FIAEC) or liquid chromatography (LCEC), with the enzyme reaction being either off-line or on-line in a reactor prior to the amperometric detector. In the second approach, the enzyme is immobilized at the electrode. Hydrodynamic techniques provide a convenient and efficient method for transporting and mixing the substrate and enzyme, subsequent transport of the substrate to the electrode, and rapid sample turnaround. The kinetics of the enzyme system can also be readily studied using hydrodynamic techniques. Immobilizing the enzyme at the electrode provides a simple system that is amenable to *in vivo* analysis. Alternatively, the transport of enzyme product from the enzyme active site to the electrode surface is greatly enhanced when the enzyme is very near the electrode. Enzyme electrodes are an extremely

important area of bioelectrochemical analysis, and many reviews are available in the literature.^[53–55]

A wide variety of enzymes have been used in conjunction with electrochemical techniques. The only requirement is that an electroactive product is formed during the reaction, either from the substrate or as a cofactor (i.e., NADH). In most cases, the electroactive products detected have been oxygen, hydrogen peroxide, NADH, or ferri/ferrocyanide. Some workers have used the dye intermediate used in classical colorimetric methods because these dyes are also typically electroactive. Although an electroactive product must be formed, it does not necessarily have to arise directly from the enzyme reaction of interest. The ability to use several coupled enzyme reactions extends the possible use of electrochemical techniques to essentially any enzyme system.

Off-Line Techniques

The simplest method of coupling enzymatic reactions to electrochemical detection is to monitor an off-line reaction using FIAEC or LCEC. The enzymatic reaction is carried out in a test tube under controlled conditions with aliquots being taken at timed intervals. These aliquots are then analyzed for the electroactive product and the enzyme activity in the sample is calculated from the generated kinetic information. Because LCEC had its initial impact in neurochemical analysis, it is not surprising that many of the early enzyme-linked electrochemical methods are of neurologically important enzymes. Additionally, the activity of lipase in pharmaceutical formulations^[56] has been determined by electrochemical means.

In addition to enzyme activity, the concentration of a nonelectroactive substrate can be determined electrochemically by this technique. By keeping the substrate (analyte) as the limiting reagent, the amount of product produced is directly related to the initial concentration of substrate. Either kinetic or equilibrium measurements can be used. Typically, an enzyme that produces NADH is used because NADH is readily detected electrochemically. Glucuronide and sulfate metabolites of pharmaceuticals^[57] and lecithin in crude drug formulations^[58] have been determined by LCEC through off-line enzymatic reaction.

Enzyme Reactors

By incorporating the entire analytical scheme (enzyme reaction and electrochemical detection) into the flow system, a great improvement in precision can be realized. Sample manipulation is minimized because only a single

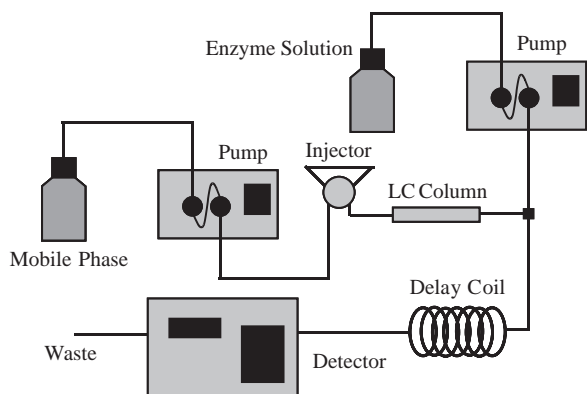

Fig. 7 General schematic of an LCEC system with an on-line enzyme reactor.

injection into the flow system is required vs. sampling of aliquots for the off-line method. Precision is also improved because the timing of the enzyme reaction and detection are much better controlled in the flow system. Finally, less of both enzyme and sample are needed with on-line enzyme reactor methods.

The simplest design for an enzyme reactor is to merely have the substrate and enzyme in two merging buffer streams followed by a reaction delay coil (Fig. 7). The delay coil can be cut to the optimum length for complete substrate conversion to product or for any desired percentage of conversion. The electrochemical detector is placed after the delay coil. Throughput is high because, even though a reaction time of several minutes may be required, several samples can be in the flow stream at the same time. Potter et al.^[59] have determined choline and acetocholine using acetocholinesterase and cholin oxidase to produce hydrogen peroxide. The hydrogen peroxide was detected amperometrically at a platinum electrode. The choline and acetocholine were separated by liquid chromatography before mixing with the enzymes. Other reports include the analysis of salicylic acid by salicylate hydroxylase,^[60] choline derived from L- α -glycerophosphorylcholine in pharmaceutical formulations incubated with glycerophosphorylcholine phosphodiesterase and subsequent post chromatographic enzyme reaction,^[61] glucuronides of fenoldopam with β -glucuronidase,^[62] sulfate conjugates of fenoldopam with sulfatase,^[62] and choline with choline oxidase.^[58]

A great savings in enzyme consumption can be achieved by immobilizing the enzyme in the reactor. In addition to the smaller amount of enzyme required, immobilization often increases the stability of the enzyme. Several designs of immobilized-enzyme reactors (IERs) have been reported, with open tubular and packed bed being the most popular. Open-tubular reactors offer low dispersion, but have a

relatively small surface area for enzyme attachment. Packed-bed reactors provide extremely high surface areas and improved mass transport at the cost of more dispersion.

Enzyme Electrodes (Biosensors)

The final method of coupling enzyme reactions to electrochemistry is to immobilize a biocatalytic material directly at the electrode surface. This biocatalytic material can be an immobilized enzyme, bacterial particles, or a tissue slice, as shown in Fig. 8. The biocatalyst converts substrate (analyte) into product, which is measured by the electrode. Electrodes of this type can be potentiometric or Faradaic, and are often referred to as "biosensors."

Biocatalytic membrane electrodes significantly expand the scope of direct potentiometry by enabling biosensors that respond to a whole host of organic substrates to be made. The selectivity of these sensors is a combination of the selectivity of the biocatalyst for the substrate and the ISE for other constituents in the sample that might reach the ISE surface membrane. Thus, the selectivity with respect to other organic constituents in the sample is determined by biocatalyst specificity, whereas the selectivity with respect to the measured analyte in the sample is determined by the underlying ISE.

A representative example of a potentiometric biosensor is an electrode for L-arginine.^[63] The bacterium *Streptococcus faecium* is immobilized on the gas permeable membrane of an ammonia electrode. Electrodes such as that for L-arginine exhibit excellent selectivity due to the high specificity of the enzyme arginine deiminase for L-arginine and the excellent selectivity of the ammonia electrode for

Fig. 8 General diagram of an electrochemical biosensor.

NH₃. The electrode responds to the concentration of NH₃ at its surface, which is proportional to the concentration of L-arginine in the sample. Nernstian plots give slopes of 40 mV–45 mV with a linear range of $1 \times 10^{-4} M$ – $6.5 \times 10^{-3} M$. The electrode is highly selective for L-arginine until contaminants grow in the biocatalyst layer, which initiates response to glutamine and asparagines. The growth of such contaminants can be discouraged under certain storage conditions.^[64] The working range of biosensors of this type is typically only 2–3 orders of magnitude with a detection limit of $10^{-5} M$ – $10^{-4} M$.

Cell-based biosensors have comparable response characteristics to enzyme electrodes, but offer several advantageous features.^[65]

- Strains of bacteria are generally less expensive than isolated enzymes. A specific sterile bacterial culture is not needed to prepare an electrode. For example, human dental plaque suffices to prepare electrodes for D(+)-glucose, D(+)-mannose, and D(–)-fructose.^[66]
- Enzyme activity is often enhanced in bacterial cells and remains longer due to the optimal environment. Consequently, lifetimes of bacterial electrodes average around 20 days compared to 14 days for enzyme electrodes. Cells can be regrown if the catalytic activity is lost.
- Bacteria can readily affect complex reaction sequences requiring cofactors. For example, an electrode for nitrilotriacetic acid (NTA) is practical only because pseudomonas bacterial cells contain all of the enzymes and cofactors necessary to execute the sequence of reactions on which the electrode response is based.^[67] The underlying gas electrode for ammonia responds to NH₃ formed in the last reaction, which is proportional to the concentration of NTA in the sample.

The concept of a biocatalytic membrane electrode has been extended to the use of a tissue slice as the catalytic layer.^[68] An example of this approach is an electrode for AMP, which consists of a slice of rabbit muscle adjacent to an ammonia gas electrode.^[69] NH₃ is produced by enzymatic action of rabbit muscle constituents on AMP. The electrode exhibits a linear range of $1.4 \times 10^{-4} M$ – $1.0 \times 10^{-2} M$ with a response time varying from 2.5 min to 8.5 min, depending on the concentration. Electrode lifetime is about 28 days when stored between use in buffer with sodium azide to prevent bacterial growth. Excellent selectivity enables AMP to be determined in serum.

Cell- and tissue-based electrodes are generally less selective than enzyme-based electrodes because many constituents of cells result in response to many possible

substrates. This problem may be solved by the use of specific inhibitors to block interfering reactions. These electrodes also suffer from long recovery times (3 hr–4 hr) after a measurement has been made. However, such electrodes may be sufficiently cheap to be disposable. Most biocatalytic membrane electrodes are susceptible to irreversible loss of activity when exposed to samples containing denaturing or toxic agents. The difficulties associated with electrode longevity, both during use and storage, have stymied the commercial development of biocatalytic membrane electrodes.

Electrodes based on the immobilization of enzymes at the electrode surface have been reported for a few pharmaceutical applications. Seegopaul and Rechnitz^[70] developed a CO₂ electrode that responds to methotrexate due to the inhibition of dihydrofolate reductase by the analyte. Additional applications have included the detection of penicillin consumption by penicillinase^[71] as well as urea by urease^[72] with a pH electrode and analysis of L-ascorbic acid by ascorbate oxidase.^[73]

Coatings of immobilized enzymes have been used with ISFET devices in a manner that is analogous to their use with the ISE. For example, an ISFET coated with penicillinase immobilized in a membrane responds to penicillin similarly to the ISE mentioned.^[74] Enzymatically coupled pH ISFETs have also been used for the measurement of urea,^[75] acetylcholine,^[75] and glucose.^[76]

The concept of combining an enzyme reaction with an amperometric probe offers all the advantages for potentiometric electrodes with a much higher sensitivity. For this reason, much effort has been applied to the development of new amperometric biosensors including significant work on pharmaceutical applications.^[77–84] Reports have included a dual-enzyme electrode for monitoring quality control of peptides in pharmaceutical formulations.^[85] This system is based on the oxidation of tyrosine by tyrosinase and reduction back by quinoprotein glucose dehydrogenase. The redox cycling of the enzyme sensor lowers the limit of detection of this sensor to $2 \times 10^{-7} M$. Additionally, the natural selectivity of lactate oxidase for the L-enantiomer was used to develop a specific biosensor capable of identifying racemic and enantiomerically pure samples.^[86]

ELECTROCHEMICAL IMMUNOASSAY

The remarkable selectivity that is inherent in the reaction of an antibody with the antigen or hapten against which it was raised is the basis for the extensive use of immunoassays. An electrode in which an antibody or an antigen/hapten is incorporated in the sensing element is

termed an “immuno-electrode.” The response of the immuno-electrode is based on an immunochemical reaction between the sensing element of the electrode and antibody or antigen/hapten in the sample solution. Immunoassay is based on the use of an antibody as a selective chemical reagent for an antigen or hapten analyte. Immunoassays are commonly categorized as heterogeneous, in which antibody-bound antigen is separated from free antigen at some point in the procedure, or homogeneous, in which there is no separation step.

Historically, most immunoassays have relied on radioisotope labeling for detection. The desire to avoid the use of radioisotopes has led to the development of alternative labels. One of the most successful alternatives has been to use enzyme labels, thus enzyme immunoassays. In enzyme immunoassays, substrate is added following the antigenic binding. Product is then detected and its concentration or rate of formation is a measure of antigen (analyte) concentration in the sample. Enzyme immunoassays can be extremely sensitive because of the chemical amplification provided by the enzymatic step. Chemical amplification is the passing of a substance through a cycling or multiplication mechanism to generate a large amount of product.^[87] In this way, a trace concentration of analyte results in a significantly higher concentration of product, which is actually detected, but is still related to the original concentration of analyte. Electrochemical enzyme immunoassay is the use of electrochemical techniques to detect the products from an enzyme immunoassay.^[88]

Potentiometric Immunoassays

Conventional ISEs have been used as detectors for immunoassays. Antibody-binding measurements can be made with hapten-selective electrodes such as the trimethylphenylammonium ion electrode.^[89] Enzyme immunoassays, in which the enzyme label catalyzes the production of a product that is detected by an ISE, take advantage of the amplification effect of enzyme catalysis in order to reach lower detection limits. Systems for hepatitis B surface antigen^[90] and estradiol^[91] use horseradish peroxidase as the enzyme label and an iodide electrode as the detector. The horseradish peroxidase catalyzes the oxidation of *p*-fluoroaniline with the fluoride detected by the ISE. Biotin^[92] and cyclic AMP^[93] have been determined using lysozyme and urease as labels. The immunoreaction between human antibody (IgG) and peroxidase-labeled antihuman IgG antibody can be detected with a fluoride electrode.^[94] Adenosine deaminase, asparaginase, and urease have been examined

as possible enzyme labels for immunoassays using potentiometric detection with the ammonia gas-sensing membrane electrode^[95] and adenosine deaminase with an NH_4^+ electrode.^[96] CO_2 electrodes have been used for the determination of human IgG^[97] and digoxin.^[98]

Heterogeneous Amperometric Immunoassays

Most heterogeneous immunoassays are run in a competitive format in which a standard labeled antigen is allowed to compete with sample antigen for a limited number of antibody sites. The ratio of standard-to-sample antigen that is bound then reflects the concentration of analyte in the sample. Another widely used assay format is the sandwich immunoassay. In this format, the antigen is “sandwiched” between two different antibodies, one of which is labeled for detection. Sandwich assays are more specific than competitive assays because two highly selective antibody reagents are used rather than one; however, the sandwich format is only applicable to antigens large enough to bind two antibodies simultaneously.

Several heterogeneous electrochemical enzyme immunoassays have been demonstrated.^[99–101] These are based on the enzyme-linked immunosorbent assay (ELISA) technique in which antibody is immobilized on the walls of a small volume plastic vessel. The ELISA technique can follow either a competitive equilibrium or a sandwich format. Both formats have been used with electrochemical detection. The general protocol for these two formats is shown in Fig. 9.

Heterogeneous electrochemical enzyme immunoassays have several advantageous features. The detection limit is typically in the low pg mL^{-1} range, and is a function of the antigen–antibody binding constant, rather than the ability to detect the enzyme product. Because the sample is rinsed from the reagent tubes before adding substrate, problems with interferences by electroactive constituents of the sample or possible electrode fouling by protein adsorption are eliminated. Finally, this technique should readily lend itself to automation for the routine analysis of many samples.

Homogeneous Amperometric Immunoassays

Homogeneous immunoassays rely on a change in the intensity of a label signal that occurs when labeled antigen binds with antibody. When the label is an enzyme, a reduction in the rate of enzyme catalysis forms the basis for the assay. This technique is commonly known as an EMIT (enzyme multiplied immunoassay technique) assay.

Fig. 9 General schematic of ELISA in competitive and sandwich formats.

This enables free, labeled antigen to be distinguished from bound antigen with no separation step necessary.

Homogeneous electrochemical enzyme immunoassays for both phenytoin^[102] and digoxin^[103] have been developed. In both cases, the label was glucose-6-phosphate dehydrogenase, which catalyzes the reduction of NAD^+ to NADH. The NADH produced was detected by LCEC. Many other homogeneous electrochemical immunoassays have also been reported.^[101,104]

The main advantage of a homogeneous immunoassay, compared to a heterogeneous immunoassay, is the absence of a separation step. This translates into a simpler procedure and easier automation. However, homogeneous assays are typically less sensitive and more easily susceptible to sample interferences which are removed in a separation step.

APPLICATIONS

Oxidative Applications

Many drugs are electroactive, and as such, have been determined using amperometry. Table 1 lists several compounds of pharmaceutical interest, which have been determined by electrochemistry. Alternatively, Jane et al. have reported the electrochemical response of some 462 basic drugs.^[105]

Phenols

Most phenolic compounds are readily oxidized at carbon electrodes. The oxidation potentials vary widely depending upon the number of ring hydroxyl groups and their positions on the ring. Many compounds of biomedical and industrial interest are phenolic and LCEC-based trace analysis determinations are quite popular.

Phenols constitute a major source of xenobiotic exposure to the body in the form of drugs and environmental pollutants. Oxidative metabolism of these compounds can lead to physiological damage; therefore, the metabolism of these compounds is of great interest. LCEC has been a powerful tool for investigating the metabolism of aromatic compounds by the cytochrome p-450 system.^[106]

Aromatic amines

Many pharmaceutical and environmental pollutants are aromatic amines. Like phenols, this class of compounds is generally oxidized at carbon electrodes. LCEC has been used to study the metabolism of aromatic amines of pharmaceutical origin.^[107]

Heterocyclic compounds

Many compounds of biomedical interest, both of endogenous and exogenous origin, are heterocyclic in structure. Many of these compounds are electroactive at potentials

Table 1 List of pharmaceutical products with electroactive structural components and reference to reported electrochemical determination

Class	Compound	Electrophore	Reference
Analgesics	Salicylic acid	Phenolic	[129]
	Acetaminophen	Phenolic	[129,132–137]
	Codeine	Phenolic	[139]
	Morphine	Phenolic	[141]
	Ciramideol	Phenolic	[143]
	Dezocine	Phenolic	[143]
	Nalbuphine	Phenolic	[145]
	Ketobemidone	Phenolic	[146]
Antibacterial	Sulfadimidine	Aromatic amine, heterocyclic	[147]
	Sulfamethoxydiazine	Aromatic amine, phenolic	[147]
	Sulfisoxazole	Aromatic amine	[147]
	Sulfamethoxazole	Aromatic amine	[147]
Antibiotics	Lincomycin	Heterocyclic	[150]
	Cephalosporins	Heterocyclic	[152]
	Penicillins	Heterocyclic	[150]
	Clarithromycin	Heterocyclic	[154]
	Erythromycin	Heterocyclic	[154]
	Gentamicin	Heterocyclic	[157]
Antidepressants	Benperidol	Indolic	[158]
	Haloperidol	Aromatic halide	[158,160]
	Desipramine	Heterocyclic, hydrazine	[130,131]
	Amitriptyline	Amine	[130,131]
Antidepressants	Imipramine	Heterocyclic, amine	[130,131]
Antihypertensives	Hydralazine	Heterocyclic	[138]
	Indoramin	Indolic	[140]
	Isradipine	Heterocyclic	[142]
Anti-inflammatory	Diflunisal	Phenolic	[144]
	Indomethacin	Phenolic, Indolic	[144]
	Naproxen	Phenolic	[144]
	Piroxicam	Heterocyclic	[144]
	Sulindac	Phenyl sulfoxide	[144]
Antineoplastics	Epirubicin	Phenolic	[148]
	Doxorubicin	Phenolic	[148]
	Flavopiridol	Phenolic	[149]
	Cisplatin	Metal center	[151]
Antipsychotics	Chlorpromazine	Heterocyclic	[153]
	Trimeprazine	Heterocyclic	[153]
	Risperidone	Heterocyclic	[155]

Psychotropic	Fluphenazine	Heterocyclic	[161]
	Perphenazine	Heterocyclic	[161]

useful for LCEC analysis. Methods for the determination of both ascorbic acid^[108] and uric acid^[109] were developed in the early days of LCEC. The important enzyme cofactors, the folates,^[110] the pterins^[111] biotin,^[112] and NADH,^[113] are all electroactive heterocycles that have been determined by LCEC.

Amino acids and peptides

While most amino acids are not electroactive at analytically usable potentials, much work is currently directed at general methods of amino acid detection by electrode surface modification or derivatization of the amino acid. Kok et al.^[114] have directly detected amino acids at a copper electrode. Several derivatization methods for amino acids have been reported.^[115,116]

The pentapeptides, met- and leu-enkephalin, have been detected in rat striatum tissue by LCEC at a glassy carbon electrode.^[117] These peptides can be detected directly because they contain an electroactive tyrosine residue. A series of endorphins, also containing tyrosine, have been detected by LCEC.^[118]

Thiols

Thiols are easily oxidized to disulfide in solution, but this reaction occurs only very slowly at most electrode surfaces. However, use can be made of the unique reaction between thiols and mercury to detect these compounds at very favorable potentials. The thiol and mercury form a stable complex that is easily oxidized. In a formal sense, it is the mercury and not the thiol which is actually oxidized in these reactions. For the LCEC determination of thiols, a Au/Hg amalgam electrode is used.^[119] Using a series dual electrode, both thiols and disulfides can be determined in a single chromatographic experiment.^[120,121] Additionally, carbon electrodes can be easily modified, for the determination of thiols, with many compounds including cobalt phthalocyanine^[122] and nickel hexacyanoferrate.^[123]

Reductive Applications

The majority of LCEC applications have used oxidative detection. This is likely because of the perceived difficulties encountered with reductive detection. In particular, dissolved oxygen and trace metal ions must be removed to prevent high background currents. These problems are not difficult to overcome^[124] and more applications of reductive detection should appear as this is more generally realized.

Nitro compounds

Aromatic nitro and nitroso compounds are easily reduced at carbon and mercury electrodes. Other nitro compounds such as nitrate esters, nitramines, and nitrosamines are also typically easily reduced. The complete reduction of a nitro compound consists of three two-electron steps (nitro to nitroso to hydroxylamine to amine). Since most organic oxidations are only two-electron processes, higher sensitivity is typically found for nitro compounds. Several LCEC-based determinations of nitro compounds have been reported.^[125]

Heterocycles

Several heterocycles of biomedical interest are reducible. Among these, the K vitamins^[126] and the pterins^[126] have been determined by LCEC. Some heterocyclic pharmaceuticals have also been determined by reductive LCEC.^[127,128]

FUTURE TRENDS

The application of microchip manufacturing technology to analytical chemistry has encouraged the development of even smaller analytical devices. Because the electrochemical detection does not suffer from a loss in performance when miniaturized, the incorporation of electrodes into microfabricated devices has received much attention. One of the greatest potentials of microfabricated analytical systems is the ability to perform a number of simultaneous parallel analyses. Because combinatorial synthesis provides a means to produce analyte libraries of a million or more compounds, the need for improved high throughput screening methodology will likely turn to microfabricated electrochemical instruments capable of simultaneously assaying many analytes. Developments in this area are hoped to provide more rugged electrochemical detectors that will further reduce to analyte and solvent consumption and as well as reduce analysis time, and provide simple, disposable instrumentation. Another potentially useful application of microfabricated separation-coupled electrochemical instrumentation would be in routine analysis. Often analytical methodology for quality control is limited by the ease with which the method can be applied at the manufacturing site. Reproducibly manufactured, disposable, integrated electrochemical instruments would simplify calibration and eliminate the need for analysts to remove and polish electrodes.

With the availability of less expensive and more dependable commercial instruments, liquid chromatog-

raphy coupled to mass spectrometry is quickly becoming the industry standard. However, the role of electrochemistry in pharmaceutical analysis has been well defined, and will likely continue to be preferentially employed in applications where low analyte concentrations, small sample volumes, or complex sample matrices requiring high specificity challenge the analytical method.

Electrical Power Systems for Pharmaceutical Equipment

Joseph Maida

Maida Engineering, Inc., Fort Washington, Pennsylvania, U.S.A.

INTRODUCTION

Electrical power systems that serve pharmaceutical equipment must be safe, reliable, functional, predictable, flexible, clean, and sometimes validated. The electrical power systems have voltages ranging from 120 to 69,000 V. Pharmaceutical plants in the United States and Canada can purchase 3 phase, 60 Hz electric power from utility companies that is more reliable than the power they could generate in house. Whereas in other countries, electric power is purchased at 3 phase, 50 Hz, and may not be as reliable as power that is generated in the plant.

This article is meant to convey a basic understanding of various power distribution system configurations and familiarize the reader with the electrical distribution equipment that are commonly installed within pharmaceutical plants in the United States. It will help in the evaluation of both new and existing electrical power distribution systems that serve pharmaceutical equipment.

ELECTRICAL POWER SOURCES

Electricity can be purchased from an energy provider or can be generated in the pharmaceutical plant. Usually, purchased electricity is cheaper than on-site generated electricity. Large plants have many options when purchasing electricity. A thorough understanding of these options can significantly reduce the electrical operating cost and will increase the reliability of the electrical power system. All plants and especially small- and medium-size plants must accurately determine their current and future normal electrical power loads and normal/emergency power loads when deciding how to purchase electricity and how to install a reliable electrical power system.

The pharmaceutical plant's electrical loads can be divided into four categories:

1. Normal loads—Loads that can be turned off for a period of time without creating a hazardous condition or causing a substantial loss of product or research.
2. Standby loads—Loads that if they lose electricity will cause a hazardous condition or cause a substantial loss of product or research but which can sustain a power interruption of 60 sec.

3. Standby noninterruptible load—Loads that cannot sustain any interruption in power.
4. Emergency loads—Legally required emergency and egress lighting and other loads classified as such by governmental agencies and locally adopted building codes.

Loads can be further divided into groups based on their utilization voltage, category, type, and location within the plant. Typical utilization voltages within pharmaceutical plants include 480/277 and 208/120 V. Categories include linear and nonlinear loads. Linear loads typically include incandescent lamps and induction motors that are not controlled by a variable frequency drive (VFD). Nonlinear loads include all loads that have switching power supplies or silicon control rectifiers such as VFDs, uninterruptible power supplies, and electronic ballasts on 480/277 V systems and personal computers, copy machines, faxes, electronic devices, and instruments on 208/120 V systems. Types include continuous loads such as lighting that stay on all day and noncontinuous loads that will not operate for more than 3 hr at a time.^[1] The areas in the plant should be divided into locations based on the function or process performed in the area and based on whether or not the area being classified is a current good manufacturing practices (cGMP) area.

The load projections should be based on a minimum of 7 years. To obtain the group demand for each group of loads, multiply the connected load for the group by a diversity factor that reflects the proportion of load that will operate at any one time to the total connected load. The sum of the group demands will equal the plant's maximum demand. After determining the maximum demand, consult with the local public utility company for assistance in determining the optimum voltage and configuration for the electrical service entrance for the plant.

The ampacity or rated current carrying capacity of the electrical service entrance conductors that connect the utility company's lines to the plant's service entrance equipment must be a minimum of 125% of the calculated maximum demand for continuous loads plus 100% of the maximum calculated demand for noncontinuous loads. Service entrance conductors and equipment with higher ratings or provisions to increase the rating of the service entrance conductors are recommended.

Large plants, which have a central utility plant (CUP) with chiller motors rated above 200 hp, should consider purchasing and in some instances distributing electricity at primary voltage levels such as 4160 V and 13,800 V.

An emergency generator should have a rating that is 25% and possibly 100% higher than the sum of the total calculated standby and emergency demand for the plant. Alternately, provisions for a future emergency generator should be provided as part of the initial installation. Discuss the type of fuel required for the generator's engine with the local authority having jurisdiction. The National Electrical Code, NFPA 70 (NEC), requires that the fuel be on site if the generator provides power for emergency loads. However, exceptions to this requirement have been permitted where reliable natural gas service is available.

ELECTRICAL POWER SYSTEM UTILITY SERVICES

Primary services are typically installed for medium and large pharmaceutical plants and can be purchased as a single service, a dual service, or a regular-reserve service (Fig. 1). The utility company will install two (2) separate power lines to the plant for a dual service and for a regular-reserve service. Each dual service power line will normally serve half of the loads in the plant but each will be capable of serving all of the loads in the plant. Regular-reserve service power lines are connected to a common

bus with only the regular power line normally serving all of the plant's loads.^[2]

Secondary services are typically installed for small- to medium-size pharmaceutical plants. They are available at the utilization voltages of 277/480 or 120/208 V. Secondary services are less expensive to install and maintain than primary services. However, the kilowatt-hour cost for electrical power supplied by a secondary service is higher.

SECONDARY CONFIGURATIONS

The following items should be considered when planning an electrical power system's secondary, less than 1000 V, configuration.

1. The utility company will provide and own the transformer that will supply secondary voltage for the service to the plant. This transformer should be dedicated to the pharmaceutical plant and should have a grounded wye secondary. Sharing a utility-owned transformer with other utility customers will reduce the quality and the reliability of the electric service to the plant.
2. The size of the utility company's transformer will affect the rating of the service entrance equipment and the starting of large motors. If the transformer rating is low, reduced voltage starting will be required for starting large motors. If the transformer rating is high, service entrance equipment will require a high symmetrical short-circuit (IAC) rating. The utility

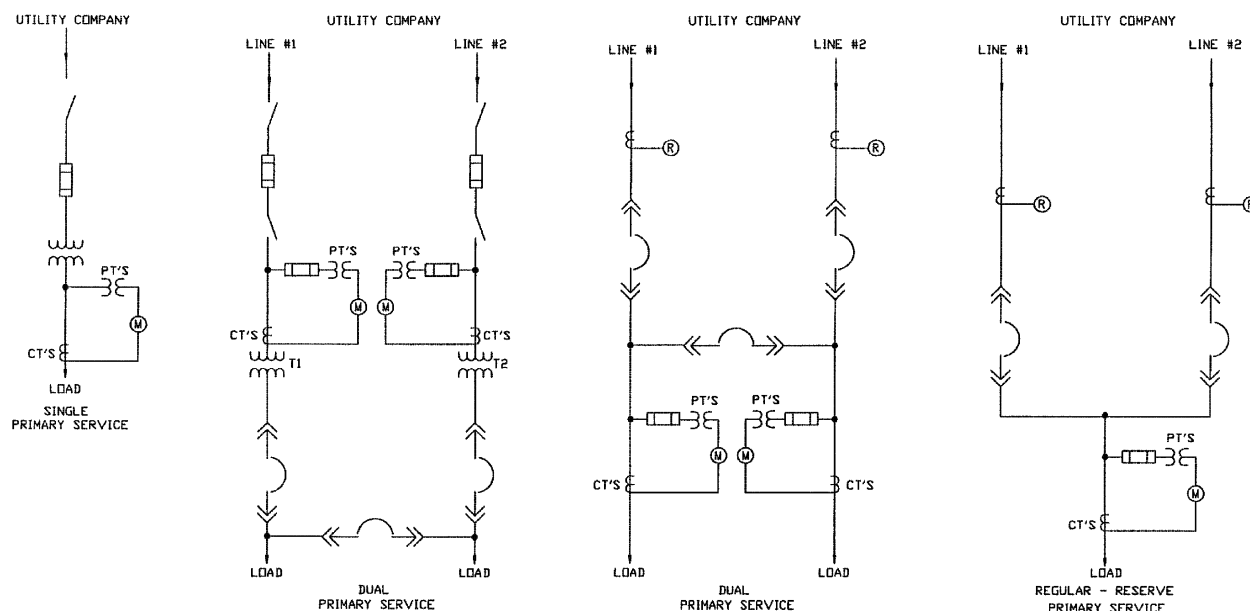

Fig. 1 Typical primary electric service arrangements.

company will provide the maximum available symmetrical short-circuit current available at the secondary of their transformer.

3. Service entrance equipment must have a current rating equal to or greater than the present and future service entrance conductors' ampacity. Moreover, this equipment must have an IAC current rating that is higher than the available short circuit current at the utility company's transformer. Spare service entrance conduits should be installed for future service entrance conductors. The service entrance equipment should include spaces for future feeder circuit breakers to supply future loads. All incoming service entrance conductors must be 3 phase, 4 wire and should be installed in underground metal conduit.
4. Service entrance equipment should be installed in an indoor electrical room whenever possible. The equipment should include one to six main service entrance power circuit breakers or load break disconnect switches and feeder circuit breakers for loads within the plant. Circuit breakers and disconnect switches for 480/277 V systems that are rated at 1000 A or more must include ground fault protection. Feeder circuit breakers will typically be molded case. Integrally fused circuit breakers are available with very high short circuit IAC ratings for both power and molded case circuit breakers. Fuses and current limiters for integrally fused circuit breakers must be stored within the electrical room.
5. Fuses should not be used to protect secondary voltage feeders. The time current characteristics of fuses above 100 A will not coordinate with the ground fault pickup currents and time delays of the main overcurrent protection (circuit breaker or fused disconnect switch) ground fault protection. A main load break disconnect switch can be equipped with current-limiting fuses to reduce the available short-circuit current from the utility and should have a three-phase voltage relay for single-phase protection.
6. Ground fault protection, including circuit breakers or relays, should be set as low as possible without causing nuisance tripping. The ground fault pickup and time delay for the main overcurrent protection should coordinate with the trip characteristics of the largest feeder circuit breaker that does not have ground fault protection and must be less than the maximum current permitted by the NEC.
7. If fuses are used in the power distribution system, three-phase motor starters should have solid-state overload devices that include single-phase protection.
8. Two (2) to six (6) separate service entrance cables connected to the secondary side of one utility owned transformer can connect to separate main circuit breakers or main load break fused disconnect switches that are mounted next to each other. The sum of the ampacity of all of the service entrance conductors must have a current rating equal to or greater than the present and future maximum demand for the plant. This approach can reduce the cost of the service entrance installation but will not provide the additional level of protection provided by having one main circuit breaker or one main fused disconnect switch. Therefore it is not as reliable.
9. A maintenance program should document all tests, inspections, and faults cleared by a main and feeder circuit breaker. Lack of such a program will reduce the reliability of the electrical equipment.^[3] Molded case circuit breakers require no internal maintenance. They should be inspected for broken casing and loose connections after they operate to clear a fault and should be replaced after they have operated to clear two faults. Feeder circuit breakers, especially older circuit breakers, should be exercised (repeatedly opened and closed) whenever possible.^[4] Part of the initial commissioning of an electrical power system must include testing of the ground fault protection.^[1]
10. The secondary selective circuit arrangement is recommended for all critical loads (Fig. 2). It requires the installation of double-ended switchgear or a variation thereof. Double-ended switchgear includes two main circuit breakers that serve separate feeder buses with a tie circuit breaker in the middle. Each feeder bus has its own set of feeder or branch circuit breakers. The load should be evenly split between each of the feeder buses.
11. Important loads can be connected to redundant feeder circuit breakers, one on each side of the double-ended switchgear, by connecting the load sides of the circuit breakers together with a feeder cable. This approach should be used with caution. Another approach is to connect the redundant feeder circuit breakers to a time-delayed automatic transfer switch.

PRIMARY CONFIGURATIONS

The following items should be considered when planning an electrical power distribution system's primary configuration.

1. A single primary service can have one to six primary service entrance circuit breakers or fused disconnect switches. These overcurrent devices will protect primary feeders that distribute power to distribution unit substations located in electrical rooms throughout the plant, to primary voltage motor starters in the

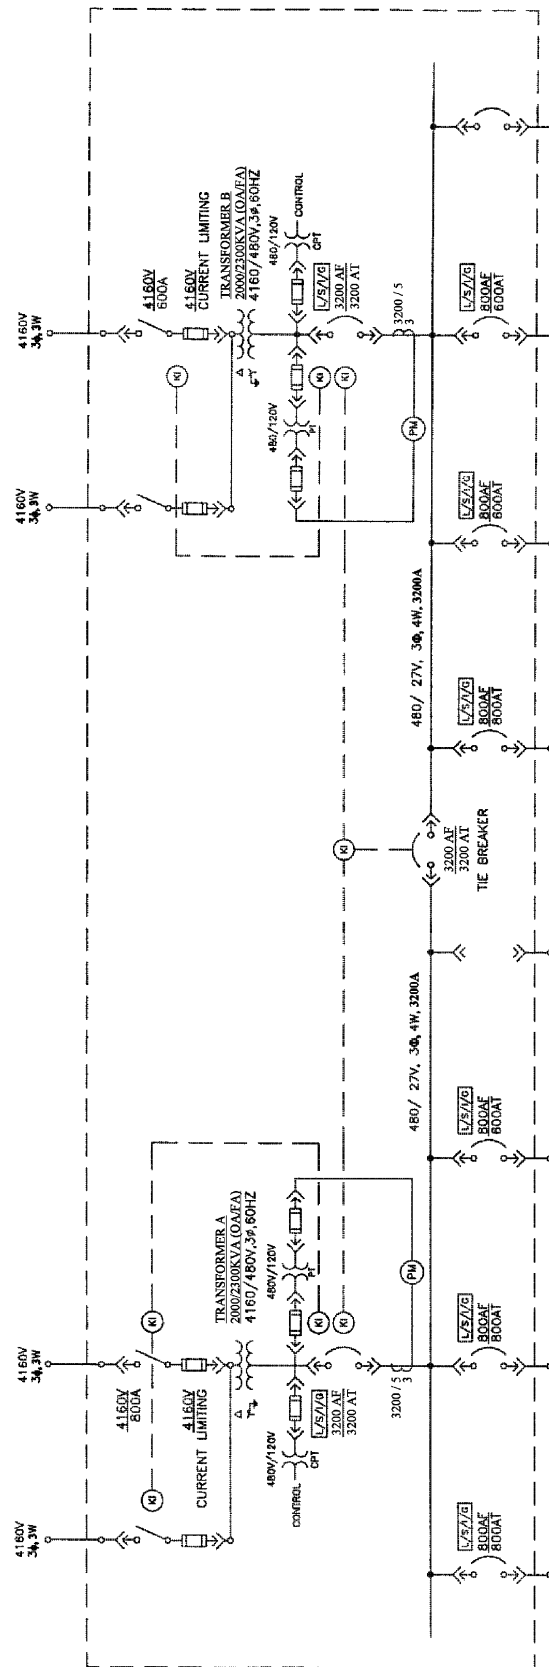

Fig. 2 Secondary selective circuit arrangement.

- CUP, and sometimes to generator switchgear when the generator system is designed for momentary or continuous operation in parallel with the utility line.
2. A dual service will have two main service entrance circuit breakers and a service entrance tie circuit breaker and may have additional primary feeder circuit breakers. A regular-reserve service will have two main service entrance circuit breakers and may have additional primary feeder circuit breakers (Fig. 1). In very large pharmaceutical plants, the primary feeder circuit breakers will connect to outdoor substation transformers that will provide 4160 V for the CUP and 13,800 V for distribution unit substations.
 3. Unit substations, each consisting of a primary fused disconnect switch or circuit breaker, a dry transformer, and secondary switchgear should be in a central location near their loads. Unit substation transformers should be sized to carry at least 125% the maximum present and future connected load.
 4. Double-ended unit substations provide economical, reliable, preengineered, and factory-tested configuration for obtaining secondary selective circuit arrangements at utilization voltage of 480/277 or 120/208 V and for installing a primary selective circuit arrangements (Fig. 2). Double-ended unit substations include one or two main primary circuit breakers or fused disconnect switches on both sides that are connected to transformers that are connected to the feeder circuit breaker sections. Each feeder circuit breaker section has a main secondary circuit breaker that protects the internal bus, which connects to the feeder circuit breaker, and is connected to the other feeder circuit breaker section through a secondary tie circuit breaker. Each transformer should be rated to carry at least 125% of the maximum present and future connected load for the entire double-ended substation.
 5. Primary selective circuit arrangements utilize two primary selectable feeders for each transformer. These feeders are either connected to the line side of two interlocked primary nonfused disconnect switches that have a common load side fuse or to the line side of two interlocked primary fused disconnect switches. The latter configuration is shown in Fig. 2. Only one primary disconnect switch can be closed at any time.
 6. Dry-type transformers are typically installed indoors and include ventilated, sealed, or gas filled, totally enclosed nonventilated, and cast coil types. Cast coil transformers are the most expensive and they have the highest overload capability. Transformers should be sized based on their air to air (AA) rating. Provisions for future automatic fans that will provide a higher force air (FA) rating and an alarm that indicates when the fans are operating due to the temperature within the transformer should be provided.
 7. If installed outdoors, pad mounted liquid filled transformers up to 2500 KVA are available with mineral oil or less flammable silicon liquids. Outdoor liquid-filled transformers sometimes have an advantage over outdoor dry-type transformers, which present a relatively difficult lightning protection problem because of their lower basic impulse levels (insulation level).^[5] Substation transformers with ratings above 2500 KVA are utilized for higher secondary voltages, including 4160 V for large motors and 13,800 V for medium voltage feeders.
 8. All configurations described herein are based on radial feeders. Radial feeders provide power to feeders for panelboards and other electrical distribution equipment within the pharmaceutical plant. Branch circuits connect to feeders and provide power to the electrical loads.

FEEDERS AND BRANCH CIRCUIT ARRANGEMENTS

Feeders originating in switchgear, panelboards, and motor control centers provide power to electrical distribution equipment within the pharmaceutical plant. Branch circuits originating in panelboards and motor control centers provide power to pharmaceutical equipment, lighting, motors, and other equipment.

1. Three phase, 3 wire or 3 phase, 4 wire power and lighting panelboards having current ratings from 100 to 1600 A may have a main circuit breaker or may have main lugs only. They will have feeder circuit breakers for other electrical equipment and/or branch circuit breakers for pharmaceutical equipment, lighting fixtures, etc. The panelboards should have an IAC rating greater than the available short-circuit current calculated at the transformer serving the panelboard. Four-wire switchgear, panelboards, and motor control centers should have a separate neutral bus and a separate ground bus. The secondary neutral of a separately derived 4 wire system should be bonded to ground at one point ahead of the main secondary circuit breaker, ideally in the transformer and not in the panelboard. Panelboard schedules and nameplates must be installed and maintained for reliability and to comply with the NEC.
2. Separately derived systems that originate at the secondary of two winding transformers including single-phase and three-phase delta-wye transformers and at the output of a wye connected generators should be connected to the power distribution system with a 4 pole automatic transfer switch (ATS) when the neutral conductor is installed in the feeder

to the ATS. This will avoid circulating ground currents that can trip ground fault relays and effect sensitive electronic equipment.

3. Secondary unit substations (120/208 V) and transformers need to be distributed throughout the pharmaceutical plant to provide 120 and 208 V branch circuits to pharmaceutical equipment. Because of their lower voltage, the length of these branch circuits should be short.
4. AC motors 1 hp and larger should be 3 phase, 460 V.^[6] Smaller motors can be 120 V, single phase. If the plant purchases power at 208/120 V, 3 phase or 240 V, 3 phase, all motors 1 hp and larger should be 200 or 230 V, 3 phase motors.
5. Motor control centers (MCCs) are typically 480 V, 3 phase, 3 wire or 277/480 V, 3 phase, 4 wire with current ratings from 600 to 2500 A. Motor control centers should be a type that have been designed for industrial applications rather than commercial applications and must have IAC ratings greater than the available short-circuit current calculated at the transformers serving the MCCs. New MCCs that are designed to incorporate intelligent starters, protective equipment, network communication, and 24 V control circuits should be considered for future pharmaceutical process applications.
6. Individual motor controllers are sometimes connected to the main switchgear when they serve large motors but are more often connected to motor branch circuits originating in the distribution panelboards or MCCs. Individual motor controllers can be full voltage nonreversing or full voltage reversing, reduced voltage, and solid state. Reduced voltage and solid state motor controllers are used when the load requires a soft start or when there is insufficient let through (short circuit) current to start the motor without causing a severe voltage drop. When controlling a piece of critical pharmaceutical equipment within a cGMP area or process, the operation of the motor controller and all of its control circuits should be part of the qualification and validation process.
7. Variable frequency drives are special types of motor controllers. They are almost always used with 480 V motors and sometimes for motors greater than 200 hp because they require less line current to deliver the same amount of torque as compared to reduced voltage starters. They are complex and require a clean, cool, ventilated environment to properly operate. Variable frequency drives vary the speed of motors, which if continuously run at a slow speed may need supplemental cooling. Motors, designed to be controlled by VFDs, should be specified. Variable frequency drives generate harmonics on their input (line side) and output (load side) motor branch circuits. Capacitors cannot be installed on the load side of VFDs. Capacitors installed on the line side of VFDs at the switchgear or MCC must have a KVAR rating that will not cause a resonant circuit at any of the harmonic current frequencies generated by the VFDs. Variable frequency drives require many parameter settings, most of which can remain at the factory default settings and all of which should be recorded. When controlling a piece of critical pharmaceutical equipment within a cGMP area or process, the operation of the VFD, its parameter settings, and all of its control circuits should be part of the qualification and validation process.
8. Custom-built control cabinets are provided for various types of pharmaceutical equipment, usually by the equipment manufacturer. These control cabinets should be UL listed or labeled, otherwise all of the wire and electrical equipment in them are subject to the requirements of the NEC. The functions controlled by these control cabinets and sometimes the equipment within the control cabinets and all of its control circuits should be part of the qualification and validation process.
9. Uninterruptible power supplies (UPSs) must be installed for all standby noninterruptible loads. Smaller UPSs that are dedicated to individual pieces of pharmaceutical equipment are usually better than a single large UPS. Because of the amount of nonlinear loads within pharmaceutical distribution systems, UPSs are the only source of clean electricity that does not contain harmonics generated by other nonlinear loads. Uninterruptible power supplies usually have parameter settings and alarms. When providing power to a piece of critical pharmaceutical equipment within a cGMP area or process, the operation of the UPS, its parameter settings, and alarms should be part of the qualification and validation process for the piece of equipment.
10. Automatic transfer switches (ATSs) are commonly used to transfer emergency and standby loads from a normal source of power to an emergency source of power. Automatic transfer switches are available at different voltages, with three or four poles, with contacts to start an emergency generator, with time delays when part of a priority load shedding circuit, with controls that will permit bumpless transfer between the normal and emergency power system, and with integral battery chargers for the emergency generator starting batteries. They can be simple or complex and are critical parts of a reliable power distribution system. Automatic transfer switches are

a latent single point of failure within normal/emergency circuits and therefore must be inspected and tested as often as possible.

GENERATORS AND EMERGENCY POWER SOURCES

A pharmaceutical plant can obtain emergency or standby electrical power from generators, rechargeable batteries, and in rare cases from a separate utility service. Uninterruptible power supplies, central storage battery system, and unit equipment all use rechargeable batteries for their emergency source of power.

1. Unit equipment (self-contained battery packs with integral or remote lamps) provide the lowest initial cost for emergency egress lighting and exit signs but require considerable maintenance.
2. Emergency generators can provide emergency power for egress lighting and exit signs and standby loads. The 1996 NEC introduced a requirement that all legally required emergency loads must be supplied by a dedicated ATS with dedicated feeders and branch circuits. Therefore installations after 1996 must have two or more ATSs when serving both emergency and standby loads. Emergency generators typically have a standby rating and sometimes have a lower prime rating. The standby rating should be used unless the generator is intended to run for weeks at a time. Standby generators can deliver 100% of their rated KW output for short periods of time to linear loads. Non-linear loads will reduce the rating of the emergency generator. Outdoor emergency generators can be purchased with subbase double-wall fuel tanks and can be installed in walk-in enclosures in sizes up to 1600 KW.

When the entire pharmaceutical plant or a large portion thereof requires emergency power, two or more generators are recommended. These generators should have a priority load shedding circuit that turns off the noncritical loads before critical and legally required loads. Emergency generators that can be synchronized with each other can also synchronize with one of the utility lines if approved and designed in accordance with the requirements of the utility company.

HARMONICS

Nonlinear loads have a distorted periodic wave form. Any periodic wave shape can be broken into or analyzed as a

fundamental wave and a set of harmonics. Fundamental wave, 60 Hz, and harmonics currents exist within the branch circuits and feeders that serve nonlinear equipment. The highest magnitudes of currents exist at the 3rd, 5th, 7th, 9th, 11th, and 13th harmonics.

1. The triplet harmonics, including the 3rd, 9th, and 15th, exists only in circuits that have a neutral conductor such as computer circuits and lighting circuits. The triplet harmonics that exist on the secondary side of a Δ -Y transformer will not be transformed to the primary side of the transformer. Transformers with K ratings of 4-50 are specifically designed to handle these harmonic currents.
2. Variable frequency drives generate harmonic other than the triplets, the highest of which are the 5th, 7th, 11th, and 13th harmonic currents, on the three-phase circuits that feed them. Drive transformers have been specifically designed for VFD loads.

A harmonic analysis should be performed before installing capacitors on a power distribution system that has a significant nonlinear load.^[5]

GROUNDING

Grounding for any electrical distribution system can be divided into two areas: system grounding and equipment grounding. These two areas are kept separate from each other except at the point where the system receives its source of power, namely the service equipment or a separately derived system (Δ -Y transformer or generator). Grounding the neutral conductor at more than one point will cause circulating ground currents that could trip ground fault relays and circuit breakers with ground fault detection and can cause noise in the electronic equipment whose enclosures are required to be solidly grounded to the electrical systems equipment ground.^[7]

CONCLUSION

Pharmaceutical plants will become more dependent on reliable electrical power because of technological advances in pharmaceutical equipment and other loads associated with cGMP areas within plant. A reliable electrical power system is not something that just happens. It requires adequate and knowledgeable planning, engineering, design, installation, testing, and maintenance. A failure to provide any one of these will lessen the reliability of the electrical power system and could

leave the plant without electricity. A pharmaceutical plant without electricity is very dark, very quiet, and very unsafe.

ELASTOMERIC COMPONENTS FOR THE PHARMACEUTICAL INDUSTRY

Edward J. Smith

Packaging Science Resources, King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

The primary function of elastomeric components used by the pharmaceutical industry, which includes both drugs and medical devices, is to protect and deliver. Elastomeric components are typically primary packaging components; that is, they are or may be in direct contact with the dosage form. They must neither interact with the dosage form nor allow the ingress or egress of materials. Elastomeric or rubber components typically provide the means for sealing parenteral containers of varying size and shape because of their unique physical properties. Elasticity particularly permits intimate contact between the closure and the relatively rigid surfaces of container openings. No other material known today has this same unique property. This property is primarily responsible for the ability of the closure to be pierced with a sharp device, such as a hypodermic needle, and then to reseal. This is an example of the delivery function of elastomeric components. Rubber closures are an essential component of the primary package for most parenteral or injectable products. Typical rubber components are pictured in Figs. 1 and 2.

In order to understand how rubber performs its unique “protect and deliver” function, it is necessary to know how rubber is compounded and manufactured.

RUBBER COMPOUNDS

Rubber, like all other primary packaging materials, is not inert. Any material used in the compounding of the rubber component may be leached into and/or chemically react with the dosage form. The basic materials used in the compounding of rubber components used by the drug and medical device industries are listed in Table 1. These materials, and the amounts used, are significantly different from those that may be used in industrial rubber belts, tires, and hoses where heat, abrasion, and solvent resistance are typically the main concern. More than one type of each material may be used in a rubber compound. For example, compounds containing two elastomers, such

as isoprene and chlorobutyl rubber, and two pigments, such as titanium dioxide and carbon black, are very common. Compounds used for parenteral closures consist of an elastomer as the base material combined chemically and physically with other necessary rubber chemicals.

The elastomer determines most of the physical and chemical characteristics of a rubber compound. Typical elastomers are natural elastomers such as natural rubber (NR), sometimes called crepe, and synthetic elastomers such as butyl (including chlorobutyl and bromobutyl), ethylene propylene diene monomer (EPDM), and styrene butadiene rubber (SBR). A list of commonly used elastomers is shown in Table 2.

In the pharmaceutical industry, natural rubber and its synthetic analog, isoprene rubber, are normally used in products that require good physical strength or that must be able to withstand multiple punctures while maintaining seal integrity. Due to the “latex sensitivity” issue, the use of natural rubber is declining. This issue is discussed in a later section. Neoprene, a halogenated form of polyisoprene, is typically used for oil-based pharmaceutical products, such as mineral oil or vegetable oil. SBR and nitrile rubber (NBR), which is used primarily for oil-based products, are specialty elastomers that are not as commonly used. Butyls and halobutyls comprise the largest segment of pharmaceutical rubber compounds, having properties that make them applicable for the packaging of many products, especially those requiring protection from moisture vapor or oxygen. Most lyophilized and powdered products require this protection, and some liquid products require protection from oxygen. EPDMs are less commonly used, though they have been selected for large intravenous (IV) stoppers. Silicones also are not often used due to their permeability to moisture vapor and oxygen as well as their relatively high cost. A list of common elastomers and their chemical structures is found in Table 3.

Curing (or vulcanizing/cross-linking) agents are chemicals used to cross-link elastomer chains into the three-dimensional (3D) network required to give a rubber component the desired elasticity. The term “vulcanization” indicates that heat is employed in the manufacturing or molding process. Common curing agents are sulfur,

Fig. 1 Typical rubber components. A) Syringe plunger. B,C,D) Sleeve stoppers. E) Abbott ADDVantage vial stopper. F) IV bag injection site. G) Serum vial stopper. H) Lyophilization vial stopper. (Photograph provided by Abbott Laboratories.)

thiurams, zinc oxide, peroxides, resins, and amines. A desirable property of pharmaceutical rubber formulations is “cleanliness,” that is, that they contain materials that neither leach nor volatilize into the packaged pharmaceutical. Sulfur-cured rubber, because it requires other chemicals to effect an efficient cure, is not usually as clean as resin-, metal oxide-, or peroxide-cured formulations. The demands of the pharmaceutical industry and regulatory agencies are such that these relatively clean cure systems are becoming more common.

Accelerators reduce the cure time considerably by increasing the cure rate. They are not catalysts because they are chemically altered and, in many cases, also react as curing agents. Common sulfur-cure accelerators are amines, dithiocarbamates, sulfenamides, thiazoles, and thiurams. Some accelerators, because of their reactivity, may form toxic compounds, such as 2-(2-hydroxyethylmercapto)benzothiazole from mercaptobenzothiazole (2-MCBT), residues of which may be extractable. Accelerators that are secondary amines may form toxic nitrosamines.

Activators, which affect the efficiency of accelerators, are commonly added. Normally these are metal oxides, such as zinc oxide or stearic acid.

Antioxidants are classified as antidegradants or age resistors. Chemically, antioxidants protect the reactive (sensitive) sites of the rubber chains against oxygen attack. Typical antioxidants are chemicals such as hindered phenols and amines. Unsaturated elastomers, such as natural rubber, require antioxidants for protection against oxidation, which causes surface cracking and loss of elasticity. Saturated elastomers, such as silicones and fluoroelastomers, are resistant to oxidation and usually require no added antioxidants. Some antioxidants are classified as antiozonants, which are designed to provide protection when high levels of reactive ozone are likely to be in the environment. A list of saturated and unsaturated elastomers is found in Table 4.

Table 1 Rubber compounding materials and their function

Material	Function
Elastomer	Base material
Curing agent	Forms cross-links
Accelerator	Affects type and rate of cross-links
Activator	Alters efficiency of accelerator
Antioxidant	Antidegradant
Plasticizer	Processing aid
Filler	Affects physical properties
Pigment	Color

Table 2 Common elastomers used in parenteral packaging components

Elastomer	% Use	Reason
Butyl/halobutyls	~80	Excellent O ₂ and moisture barrier
Natural/isoprene	~10	Excellent physical properties such as reseal
EPDM	~5	Good heat resistance and surface lubricity
Nitrile and neoprene	~3	Resistance to vegetable and mineral oils
SBR	~1	Blended with isoprene/NR or halobutyls to improve physical properties
Silicone	≤1	Excellent heat resistance; poor O ₂ and moisture barrier; high cost

Table 3 Chemical structures of common elastomers

Common name	Chemical name	Structure
Butyl rubber	Poly(isobutylene-isoprene)	$\left[\text{CH}_2 - \underset{\text{CH}_3}{\overset{\text{CH}_3}{\text{C}}} \right]_{50} \left[\text{CH}_2 - \underset{\text{CH}_3}{\text{C}} = \text{CH} - \text{CH}_2 \right]_n$
Halobutyl rubber ^a	Halogenated poly(isobutylene-isoprene)	$\left[\text{CH}_2 - \underset{\text{CH}_3}{\overset{\text{CH}_3}{\text{C}}} \right]_{65} \left[\text{CH} = \underset{\text{CH}_3}{\text{C}} - \overset{\text{X}}{\text{CH}} - \text{CH}_2 \right]_n$
Ethylene-propylene rubber	Poly(ethylene-propylene)	$\left[\text{CH}_2 - \text{CH}_2 \right]_3 \left[\text{CH}_2 - \underset{\text{CH}_3}{\text{CH}} \right]_n$
Ethylene-propylene-diene rubber	Poly(ethylene-propylene-diene)	$\left[\text{CH}_2 - \text{CH}_2 \right]_{15} \left[\text{CH}_2 - \underset{\text{CH}_3}{\text{CH}} \right]_5 \left[\text{diene} \right]_n$
Silicone rubber	Polydimethylsiloxane	$\left[\underset{\text{CH}_3}{\overset{\text{CH}_3}{\text{Si}}} - \text{O} \right]_n$
Urethane rubber	Adipic acid-ethylene glycol polyester	$\text{HO} - (\text{CH}_2)_2 - \text{O} - \overset{\text{O}}{\parallel} \text{C} - (\text{CH}_2)_4 - \overset{\text{O}}{\parallel} \text{C} - \text{O} - (\text{CH}_2)_2 - \text{OH}$
Fluoroelastomers	Polytetrafluorethylene	$\left[\underset{\text{F}}{\overset{\text{F}}{\text{C}}} - \underset{\text{F}}{\overset{\text{F}}{\text{C}}} \right]_n$
Natural rubber	<i>cis</i> -(1,4-Polyisoprene)	$\left[\text{CH}_2 - \underset{\text{CH}_3}{\text{C}} = \text{CH} - \text{CH}_2 \right]_n$
Polyisoprene rubber	<i>cis</i> -(1,4-Polyisoprene)	$\left[\text{CH}_2 - \underset{\text{CH}_3}{\text{C}} = \text{CH} - \text{CH}_2 \right]_n$
Neoprene rubber	Polychloroprene	$\left[\text{CH}_2 - \underset{\text{Cl}}{\text{C}} = \text{CH} - \text{CH}_2 \right]_n$
Styrene-butadiene rubber	Poly(butadiene-styrene)	$\left[\text{CH}_2 - \text{CH} = \text{CH} - \text{CH}_2 \right]_4 \left[\text{CH}_2 - \underset{\text{C}_6\text{H}_5}{\text{CH}} \right]_n$
Nitrile rubber	Poly(butadiene-acrylonitrile)	$\left[\text{CH}_2 - \text{CH} = \text{CH} - \text{CH}_2 \right]_5 \left[\text{CH}_2 - \underset{\text{CN}}{\text{CH}} \right]_2$
Polybutadiene	Polybutadiene	$\left[\text{CH}_2 - \text{CH} = \text{CH} - \text{CH}_2 \right]_n$

Table 4 Saturated and unsaturated elastomers

Saturated	ASTM abbreviation	Unsaturated	ASTM abbreviation
Butyl	IIR	Natural	NR
Halobutyls (chlorobutyl and bromobutyl)	CIIR, BIIR	Isoprene	IR
Ethylene-propylene-diene monomer rubber	EPDM	Styrene butadiene	SBR
Silicone	Q	Nitrile	NBR
Urethane	U	Neoprene	CR
Fluoroelastomers	FKM	Polybutadiene	BR

Plasticizers are used in rubber compounds to assist in the mixing or molding of the rubber, to soften the final vulcanized rubber, or to add surface lubricity to the surface of the rubber component. Examples are paraffinic wax, silicone oil, paraffinic and naphthenic oils, phthalates, and organic phosphates. Silicone oil is commonly used in syringe pistons that must slide freely within a glass or plastic barrel; it also reduces the coring or fragmentation tendency of vial stoppers.

Fillers are materials that modify rubber characteristics (e.g., hardness) and improve its physical characteristics (e.g., tensile strength), in addition to reducing costs. Rubber is sometimes compounded without the use of fillers; the resultant product is called “gum rubber.” Typical fillers are calcined and hydrated clays, magnesium silicate (talc), magnesium oxide, and silicas. Carbon black, a common filler used to increase the heat resistance in industrial components such as tires, is not used as a filler in pharmaceutical components but it is used in smaller amounts as a black pigment. Polynuclear aromatic (PNA) hydrocarbons are a concern with carbon blacks but the grades used by manufacturers of pharmaceutical components contain very low concentrations.

The pigments used are inorganic salts and oxides, carbon black, or organic dyes that are used for aesthetic or functional purposes (e.g., identification, designating a dosage, etc.). Typical pigments are carbon black, titanium

dioxide, and iron oxide. With these three pigments white, black, red, and many shades of gray and pink can be produced. These pigments are chemically pure and stable, nontoxic, and relatively inexpensive. Other pigments such as phthalocyanines and ultramarine blue can be used for blues and greens, but their color fastness is not as good as the aforementioned pigments.

A typical thermoset rubber compound is shown in Table 5. In terms of percentage by weight, the elastomer and filler are the chief materials used, accounting typically for over 90% of a compound. However, the other “minor” materials are quite necessary in order for the compound to have the necessary chemical, physical, and toxicological properties required for a functional packaging component. For example, without the curing agent the compound would remain a physical mixture of materials that would have the consistency of chewing gum. On the other hand, materials such as pigments may be omitted from the compound with only minor consequences — i.e., the loss of the desired color.

SELECTION OF COMPOUND MATERIALS

Many materials may be used in a rubber compound; however, only a fraction of materials are acceptable in components used for the drug industry. A source of

Table 5 Typical thermoset rubber compound

Material	Percent by weight
Chlorobutyl rubber (elastomer)	52.7
Calcined clay (filler)	39.4
Paraffinic oil (plasticizer)	4.4
Titanium dioxide (pigment)	1.1
Carbon black (pigment)	0.13
Thiuram (curing agent/accelerator)	0.14
Zinc oxide (activator)	1.6
2,6-Di-tert-butyl-4-sec-butyl phenol (antioxidant)	0.53

acceptable materials is the U.S. Code of Federal Regulations (CFR). Since the CFR has no list for drug contact, the drug industry uses the CFR list designated for foods. Applicable sections of 21 CFR are as follows:

Section 175—Indirect Food Additives

Sections 177 and 178—Indirect Food Additives Polymers

Sections 182, 184, 185—Generally Regarded as Safe (GRAS) Lists

Section 177.2600—Rubber Articles Intended for Repeated Use (The primary section containing a list of materials used in rubber formulations for pharmaceutical items.)

There are some cautions with the CFR lists. First, manufacturers may not always submit materials to the Food and Drug Administration (FDA) for listing in the CFR. They may not want to take the time or incur the costs if they see only a limited market for their material in the pharmaceutical or food market. Second, some materials, such as 2-MCBT, which is not permitted by the FDA, are listed but are strongly discouraged. Finally, some materials listed in the CFR, such as food, drug, and cosmetic dyes, are really not applicable for rubber compounds used for pharmaceuticals. Many of these dyes are water-soluble and are not applicable for rubber formulations that come in contact with aqueous solutions, since the dyes could be extracted from the rubber and discolor the drug.

Component manufacturers may use materials not listed in the CFR provided that acceptable toxicity data is available to the reviewing health authority.

TYPES OF RUBBER AND THE MANUFACTURING PROCESS

Elastomeric closures for parenteral products are made from two types of elastomers or rubbers. Thermoset rubber, the most common, undergoes a chemical reaction during the molding or component-forming processing. In this chemical reaction cross-links, or bonds are inserted between the long polymer chains to form a resilient 3D network. Without these cross-links elastomeric closures would have properties resembling those of chewing gum, which is an uncross-linked rubber blended with sugar, flavors, and food coloring. The cross-linking process is not reversible. Once a closure is molded it cannot be remolded into another shape or size. Addition of heat only causes degradation or reversion of the rubber.

Another type of rubber that is used frequently is thermoplastic rubber (1, 2). Components are fabricated in a process that is similar to that used for common hard

plastics, such as polyethylene or polystyrene, but the final product is an elastic material with properties otherwise equivalent to those of thermoset rubbers. No chemical reactions are involved in the processing of a thermoplastic rubber. The fabrication process consists of heating the rubber compound until it liquefies, injecting the liquid into a mold, cooling the mold, and finally removing the closure from the mold. The process is reversible. Closures can be remelted and remolded into different shapes or sizes as desired. Cross-linking in this case is not a chemical process but a physical intertwining of polymeric chains. The resulting intertwined 3D network gives thermoplastic elastomers their elasticity and resiliency.

Currently, thermoplastics account for less than 5% of the elastomeric closures for parenterals. Their limited resistance to heat deformation under stress during autoclave sterilization is the main reason for this limited use. However, thermoplastics have two advantages over thermosets. First, they are chemically less complex and therefore less prone to interact with parenteral medications, and second, they may be manufactured by a simpler and more automated process. Thermoplastic elastomers have found use in baby bottle nipples and dropper bulbs that are not typically heat sterilized under compression.

The manufacturing of rubber components for pharmaceutical applications is a multistep process with controls on each step. Fully validated processes are now common. The process is outlined in Table 6.

There are generally three molding processes used for manufacturing pharmaceutical closures: compression molding, injection molding, and transfer molding. The choice of molding method usually depends on the necessary final dimensional tolerances of the item being molded. Injection molding gives the best dimensional tolerances; however, it is usually the most expensive technique, especially as compared to compression molding. Thermoset rubbers are commonly compression or transfer molded, while thermoplastic rubbers are typically injection molded. The compression molding cycle is illustrated in Fig. 3. Sheets of molded components vary in shape from round to rectangular, and in size from 12 in. in diameter to 36 × 36 inches square, and may contain 50–10,000 components.

A recent trend in rubber component manufacturing is the production of “preprocessed” components. Components are prepared for shipment in either one of two states:

1. *Ready to Sterilize (RtS)*: Typically components are washed, then rinsed with Water For Injection (WFI) to reduce bioburden and endotoxin levels, lubricated with

Table 6 Manufacturing process for rubber components for pharmaceutical use

Process step	Comment
1. Raw material specifications and testing	Tests for identity and purity
2. Weighing of batch ingredients according to DMF-filed “recipe”	Weighted to ±0.2% of nominal batch weight
3. Mixing to get homogeneous batch of material	Mixed either in an internal mixer or on an open mill
4. Testing representative samples of the mixed batch of rubber	Blend of ingredients is tested for cure characteristics; molded test piece is tested for common attributes such as durometer hardness, specific gravity, percentage ash, IR spectrum of pyrolyzate, and UV spectrum of an aqueous extract.
5. Preform material by extrusion, calendering or pelletizing	Material is formed into blocks, trips, sheets or pellets for ease of handling
6. Preformed material is placed on mold or into mold feeder mechanism	
7. Molding by compression, transfer, or injection techniques	Unvulcanized mixtures of materials are shaped into the desired component by heat and pressure; chemical reaction causes cross-links to form between polymer chains
8. Trimming	Convert molded sheets of connected components into individual components
9. Washing	Remove particulate matter, and mold and trim lubricants
10. Rinsing	Reduce surface endotoxins and bioburden when WFI water is used
11. Sterilization	Only done when presterilized components are produced
12. Final QC testing	Tests for identity, dimensional measurements, and physical, chemical and biological tests
13. Packing	A counted number of components are placed in containers, usually bags made of polyethylene or Tyvek®, then sealed in cardboard cartons for shipping
14. Shipping	Cartons are grouped by lot number, palletized and shipped by truck, ship or air

silicone oil, and finally packaged in a classified area (Classes 100–10,000) in Tyvek® bags that can be steam sterilized by the drug or device manufacturer

Fig. 3 Compression molding cycle.

before use. Alternately polyethylene bags may be used if the end user is utilizing gamma radiation for sterilization.

2. *Ready to Use (RtU)*: The process is identical to that used for RtS components except that the component manufacturer takes responsibility for component sterilization and the sterilized components are received by the drug or device manufacturer. No additional component processing is required before use.

Both processes typically require extensive validation by the component manufacturer, a description of the process in a Drug Master File (DMF), quality audits by customers, and perhaps FDA approval before RtS or RtU components are utilized. Nevertheless, RtS and RtU are trends that are moving rapidly; most major rubber component manufacturers now market RtS components (3). A list of pharmaceutical rubber manufacturers is shown in Table 7.

STERILIZATION OF RUBBER COMPONENTS

Heat, radiation, and sterilizing gases may be used to sterilize rubber components. However, components, especially vial stoppers, are most frequently sterilized by pressurized steam (autoclaving), a highly effective method and probably the most reliable of available methods when an F_0 value of at least 8 min is reached (4). However, the poor thermal conductivity of rubber and the relatively large mass of wet stoppers placed in a stainless steel container for sterilization require a careful validation of the process. Assurance must be obtained that the moist heat penetrates throughout the mass of stoppers so that every stopper receives a dose equivalent to a minimal F_0 of 8 min. However, rubber closures subjected to elevated temperatures or extended heating even at moderate temperatures degrade or revert, which is most frequently evidenced by stickiness. Therefore, the application of moist heat must be controlled because this degradation is most likely to be greatest at the outer layers of the mass of stoppers. This undesirable effect can be markedly reduced by distributing the stoppers in a shallow tray or otherwise reducing the mass, thus making it possible to reduce the thermal cycle time and the applied heat. Cycle times of 121°C for 30–60 min are usually well tolerated by rubber components made from butyl or halobutyl rubbers. Natural and isoprene rubbers are less tolerant. Increasing the sterilization temperature above 121°C or the time above 60 min is not recommended unless components have been tested to assure that no significant degradation will take place. Dry heat sterilization or drying of components above 105°C is also not recommended without prior testing. Testing may include inspection of the surface for cracks or tackiness, swelling studies to determine state of cure, functional tests such as coring and reseal, and chemical tests such as the United States Pharmacopoeia (USP) protocol or extraction studies performed before and after the sterilization cycle.

Under the usual autoclaving conditions, moist heat does not destroy pyrogens. For closures to be pyrogen-free, a final rinse with WFI before sterilization is necessary.

Ethylene oxide, a sterilizing gas, may be used to sterilize rubber components when they are part of a medical device; however, the gas is readily absorbed by the rubber and sufficient time must be allowed after sterilization for the concentration of residual ethylene oxide to dissipate to acceptable levels (5, 6).

Radiation sterilization, by either gamma or e-beam, also may be utilized to sterilize rubber components. However, some elastomers, such as butyl, chlorobutyl, and bromobutyl, do not tolerate high doses of radiation, while others,

such as natural, isoprene, neoprene, and nitrile rubbers are readily radiation-sterilized without degradation (7, 8). The challenge with radiation sterilization of rubber components in bulk (i.e., cartons or bags) is to obtain a uniform dose of radiation throughout the entire package—enough of a dose to assure the desired sterility assurance level (SAL), usually 10^{-6} , without degrading the components, especially those nearest the radiation source. There are generally two approaches that can be followed. One is to target a uniform dose of 25 kGy, which is generally accepted to assure sterility, while the other is to follow the ANSI/AAMI/ISO 11137:1994 standard and target a dose of radiation that is dependent on the bioburden of the components (9). The first approach is usually overkill but may be acceptable for radiation-resistant rubbers. The second approach usually results in lower doses applied, which may be critical with butyl and other rubbers that are not so radiation resistant. There are several necessary steps if the ANSI/AAMI/ISO standard is used. These are:

- Selection of the SAL, usually 10^{-6}
- Determination of the average bioburden from samples taken from three consecutive production lots
- Establishment of the Verification Dose. This is the dose in kGy found in Table B.1 of the standard that will give a SAL of 10^{-2}
- Confirmation of the Verification Dose by irradiating 100 components and testing each for sterility. No more than two positives are permitted
- Establishment of the Sterilizing Dose from Table B.1 of the standard
- Dose mapping, using dosimeters, on a shipping container filled with components. Irradiate and determine the maximum and minimum doses (D_{\max} and D_{\min}) received in the container
- Calculation of the Target Dose by multiplying the Sterilizing Dose by the ratio, D_{\max}/D_{\min} . The Target Dose is typically increased 6% or more to account for dosimeter error and to add additional sterility assurance.

TESTS AND STANDARDS

In-Process Tests

Several tests may be performed on unvulcanized rubber or on standard-shaped test specimens to measure the properties of a rubber compound (10). These include the following:

1. *Rheometer measurements* measure cure and cure rate characteristics of the rubber. The component

^aAbbreviation for reference use in this chapter only.

manufacturer performs this test on unvulcanized rubber. The rheometer measures the viscosity of the rubber as a function of time at a constant temperature. As time increases, the degree of cure or cross-linking increases and thus the viscosity increases.

2. *Durometer hardness* is measured on tests specimens that meet specific standards for shape and thickness (11). Durometer hardness is usually measured using the Shore A scale, which measures relative hardness on a scale of 0 to 100 units. Most rubber components for medical use are found in the 35–60 range with 40–50 typical for rubber vial stoppers. Durometer Hardness may be measured on some actual components if they have a sufficiently large flat surface and thickness, i.e., 28–32 mm IV stoppers.
3. *Compression set* is commonly used as a measure of the dimensional recovery of a rubber compound after compression at a defined level, usually 25%, at a specified time and temperature, usually 24 h at 70°C (12). High compression set values are associated with rubber that “takes a set” or loses its ability to spring back after compression. Low compression set is important for rubber closures and syringe plungers that are heat sterilized while under compression and remain under compression for long periods of time before use but must remain elastic and resilient to maintain seal integrity. Compression Set is measured on dimensionally defined test specimens.
4. *Tensile, modulus, and elongation* are measures of the strength of a rubber compound (13). They are measured on bow tie-shaped specimens that are clamped in a tensile measuring apparatus and stretched.
5. *Water vapor and oxygen transmission (WVT and O₂T)* are commonly measured on thin-film specimens. Butyl and halobutyl compounds have very low WVT and O₂T rates, while rates for natural and isoprene rubbers are higher and for silicone even higher.

Finished Component Tests

Finished component tests may be divided into three categories: those used as routine identity and/or quality control tests, those tests recommended or mandated by government, standards, and compendial groups, and those test that are part of the larger rubber component acceptance and drug/device approval process. In many instances, a test may fall into more than one category.

Identity and quality control tests (14, 15)

Percentage ash is a measure of the nonvolatile materials in a rubber formulation, such as clays and other fillers.

Specific gravity is a measure of the type and quantity of fillers in a formulation.

An *infrared spectrum* of a compound pyrolysate identifies the elastomer qualitatively (natural, butyl, etc.).

An *ultraviolet (UV) spectrum* of an aqueous rubber extract identifies and quantifies the antioxidants, curing agents, accelerators, and other UV-absorbing species extracted from the compound.

Percentage swelling in an organic solvent is a measure of the degree and consistency of cure or cross-linking that determines the physical and functional properties of a component.

These five tests may be used to characterize a rubber formulation or serve, either individually or in combinations, as quality control tests.

Compendial, standard, and government tests

The most influential of these test protocols are the USP (16), the *European Pharmacopoeia* (EP) (17), the *Pharmacopoeia of Japan* (JP) (18), the Organization for International Standardization (ISO) (19), and the Parenteral Drug Association (PDA) (15, 20). USP<381>, *Elastomeric Closures for Injections*, contains five chemical tests and two biological tests. Closures must meet the biological requirements but there are no current specifications for the chemical tests. All USP chemical tests are commonly performed on aqueous extracts but isopropyl alcohol and the drug product vehicle are also permitted. A brief description of the USP<381> tests follows (21).

Turbidity. The clarity of the closure extract is measured with a nephelometer with appropriate standards. Turbidity is a measure of the insoluble extractables from a closure and is affected by the type and amounts of ingredients in a formulation, pretreatments such as washing, extractions, sterilizations, and degree of cure. *Reducing agents.* Organic extractables oxidizable by iodine are determined in this procedure. It is affected by the same variables as turbidity.

Heavy metals. Extractable lead as well as other metals, such as zinc and cadmium, are determined colorimetrically or by atomic absorption.

pH change. The pH of the extract is a measure of the acidic and alkaline water-soluble extractables from a compound.

Total extractables. The sum of the inorganic, organic (nonvolatile), soluble, and insoluble extractables is measured in this test. The weight of total extractables is an indication of the “cleanliness” of a formulation.

Biological tests. USP 24 lists two levels of biological tests—the in vitro tissue culture test and the in vivo systemic injection and intracutaneous tests. A parenteral

closure must pass either type of test to meet USP requirements.

The application of numerical specifications to the USP <381> chemical tests is under discussion and probably will become effective in USP 24 via a supplement. The JP, EP, and ISO have specifications for rubber closures and these test protocols are compared with the USP in Table 8. Not all pharmacopeias and standards groups designate the same tests; therefore, it is important to consult a wide spectrum of references to design a test protocol for specific applications and geographical submissions. Of the four protocols compared, the JP is the most stringent in terms of limits for extractables. The USP, EP, and ISO test protocols are based on a specific closure “area” per volume of water in the extraction step. The JP test protocols, on the other hand, are based on a specific “weight” of closures per volume of water. This difference makes it more difficult for smaller closures than for larger closures in the same rubber compound to meet JP specifications; i.e., 13-mm closures will be less likely to meet JP specifications than 20-mm closures, and 20-mm closures are less likely than 28-mm closures to meet JP specifications.

Although packaging components, such as vial closures, syringe plungers, and needle shields, may meet all compendial and accepted standards, this does not mean that they will be acceptable for use with any specific drug or device. Specific evaluation tests must be performed for that purpose. Compendial and standard tests should be regarded as the first necessary but not sufficient hurdle in the race to gain approval of a component for use with a drug or device.

Specific tests for component evaluation and regulatory approval

There are three requirements for a rubber component:

1. Compatible with the drug
2. Meets functional requirements
3. Provides closure-container seal integrity

Many factors influence the choice of a rubber compound for a particular drug, the most important of which is the solvent vehicle. If the solvent vehicle is an aqueous material, then a butyl, natural, or EPDM may be used. If the solvent vehicle is an oil, then a neoprene or nitrile is utilized.

Configuration is also important and is determined by the required function. A lyophilization stopper, designed to keep out moisture, almost certainly requires a butyl formulation, while a vial stopper for aqueous-based solutions could be formulated from isoprene rubber.

Some preservatives are especially reactive with rubber. Bromobutyl rubbers, but not chlorobutyls, are recommended for drug formulations that contain chlorobutanol. A pH that is either very low or very high affects rubber formulations more than a pH in the range of 5–8. Buffer systems may also affect the choice of rubber formulations. Materials such as phosphates not only attack the rubber at high pHs but also may attack glass as well.

Metallic sensitivities affect compatibility, as drug formulations that are sensitive to divalent cations, such as calcium, zinc, or iron, may not be able to use certain rubber compounds that are cured or pigmented with these materials.

An obvious factor is the need for oxygen or moisture vapor protection. A butyl-based compound is normally chosen whenever protection from materials transmitted either into or from a drug product is required.

When it comes to color preference, most rubber manufacturers of closures used for drugs prefer to use three pigments: iron oxide to produce reds, carbon black for blacks, and titanium dioxide for whites; combinations of these are used for pinks and grays. Organic materials used as pigments are not generally acceptable since they are not very heat stable and are generally more toxic than the three pigments mentioned.

Choice of sterilization method is extremely important in choosing a rubber formulation. Many heat-sensitive drugs, such as proteins, are packaged aseptically; that is, the rubber closure, the vial, and drug are sterilized separately, and then all three items are brought together in a sterile environment to form the final package. The FDA, however, encourages terminal sterilization. In this method, the three materials are brought together and then the entire package, the drug in contact with the vial and closure, is sterilized by heat. This method is much more demanding on the closure than aseptic processing.

Radiation (Co-60) is used to sterilize many rubber items, especially those used in devices. The effect of gamma radiation on rubber closures is a function of the elastomer, dose, and postirradiation time. NR and isoprene are much more resistant to irradiation effects than butyl.

To give the drug manufacturer a high degree of assurance that the closures being investigated for a possible package will be acceptable, a prescreening procedure is commonly used by component suppliers. In this procedure, information and a sample of the drug are obtained from the drug manufacturer. Then three to five possible closures, along with an inert control stopper (a Teflon[®] plug or coated closure), are used to package vials of the drug. The closures are put onto the drug-containing vials using an exaggerated closure area-to-volume ratio (2× to 3× the normal ratio). Vials are stored at higher and/or lower temperatures than

the drug package will normally experience in the upright, inverted and on-side positions.

An inert control stopper should be used since a drug may be stable against glass but not against uncoated rubber. Only when an inert control is used will it be possible to determine whether the rubber and/or glass vial is the cause of the drug instability. Ampoules do not make good controls for the prescreening of drugs in vials since the glass for vials may be different from that used for ampoules.

Table 9 summarizes the important drug compatibility factors that must be considered when choosing a rubber component for a specific drug/device application. These factors along with the functional and seal integrity requirements can be used to write specifications for components. The packaging engineer, as with the rubber compounder, faces the challenge of choosing a compound that best meets the overall requirements but, only at best, provides a balance of all the actual chemical and functional needs. For example, an engineer may choose

an isoprene vial closure because multiple punctures with a large cannula are required. Isoprene will provide the low coring and excellent reseal required. But the engineer may give up some shelf life since isoprene is a poor oxygen barrier. Choosing a butyl closure would give additional shelf life due to its better barrier properties, but coring and reseal would not be acceptable. Closure compound choice is always a give-and-take proposition where drug/device requirements must be prioritized before the choice of a rubber compound can be made. Table 10 lists important physical and chemical properties of elastomers (22).

There are four general types of closure–drug interactions:

1. Adsorption occurs when a drug is concentrated at the surface of a closure or vial.
2. Absorption occurs when a drug material is dispersed in the closure matrix.
3. Permeation is the transmission of a drug ingredient through a closure into the atmosphere or transmission of an outside material into the container.
4. Leaching is the process by which closure ingredients are extracted into the drug product.

All four of these interactions commonly occur. No rubber compound is absolutely inert to a drug. In many cases, the extent of the particular interaction is extremely small and may not be measurable, but generally all four are occurring, albeit at a low rate. With proteins, adsorption can be a problem. Many proteinaceous materials made by the biotechnology industry are highly adsorbent onto rubber surfaces and their potency may be readily lost. Other drugs products, especially ones that are very acidic or basic, may attack the stopper and cause the extraction of rubber compound ingredients. Common leachables from rubber closures include low molecular weight elastomer fragments, metal ions, antioxidants, plasticizers, lubricants, curing agents, and accelerators. The rate and relative importance of these four interactions determines the degree of compatibility or incompatibility of a stopper with a drug product.

In May 1999, the FDA issued an updated guidance entitled “Container Closure Systems for Packaging Human Drugs and Biologics—Chemistry, Manufacturing and Controls Documentation,” that listed in tables the packaging information that should be submitted in an application (23). The guidance divides the information into four sections:

1. *Description*—Overall general description of the container-closure system plus specific information on suppliers, materials of construction, and postmanufacturing treatments.

Table 9 Drug compatibility factors affecting the choice of rubber component

Liquid or solid?
Liquid
1. Aqueous—pH, preservative, buffer cosolvent?
2. Oil—Vegetable or Mineral?
Solid
1. Lyophilized or powder fill?
Configuration?
Need for O ₂ , H ₂ O, CO ₂ protection?
Drug type?
Metallic sensitivities?
Method of closure and package sterilization?
Color preference?

2. *Suitability*—This section prescribes that tests must be done to assure protection of the drug product, safety of the packaging component material, compatibility of the component with the drug product, and performance of the component.
3. *Quality control*—The rubber component manufacturer’s release criteria and drug packager’s acceptance are found in this section. Also recommended is a method to monitor the consistency in composition of elastomeric components such as periodic extraction profiles.
4. *Stability*—Testing of the drug product using the packaging component is required. Unlike compendial tests that utilize water for extraction studies of the packaging component, the complete drug product is utilized in these stability studies.

This guideline advocates more information on rubber extractables and the proper use of DMFs.

Knowledge of extraction data from elastomeric components refers not only to the broad (and usually nonspecific) type of extractable data generated in USP<381> testing, but also to the identification and quantification, where necessary, of specific extractable species. Example of nonspecific extractables include turbidity, reducing agents, heavy metals, pH change, and total extractables; They all measure broad types of extractables. Specific extractables include inorganics, such as zinc or lead and organics, such as PNA, stearic acid, nitrosamines, tetramethylthiuram disulfide, or 2,6-di-*tert*-butyl-4-*sec*-butyl phenol. Both liquid (HPLC) and gas chromatography (GC) are well suited for this purpose (24). Drug/device producers who utilize elastomeric packaging components require information from their suppliers on extractables (extractable profiles), including test methods, that are generated in water at various pH values (i.e., 3, 7, and 10) and in organic solvents such as isopropanol.

^aRatings adapted from Ref. 22.^bRatings expressed are typical for rubber compounds made from the elastomers; they can vary significantly from compound to compound.^cND, not determined.

Armed with this information, they can look for extractables in their drug products.

Confidential packaging component information, such as the compound recipe, may be placed in a Type III DMF so that the FDA can review the information when it reviews the drug application (IND, NDA, ANDA, or BLA) (25). Most elastomeric compounds are filed at the request of a pharmaceutical manufacturer who has chosen to use the rubber closure in one or more drug packages or devices applications. The name of a rubber compound is associated with a precise recipe that designates specific ingredients and quantities. Once a rubber compound is filed in a DMF, no changes can be made in that compound without changing the DMF and notifying all customers on whose behalf the DMF was accessed and reviewed by the FDA. Since changes in a supplier's DMF may require additional stability studies by the drug manufacturer, changes are infrequent.

RECENT ISSUES AND DEVELOPMENTS

Latex Sensitivity

There are medical and regulatory issues surrounding the use of "latex rubber" due to allergic reactions that have resulted in medical emergencies. Even deaths have been noted (26, 27). There are two broad types of rubber—natural and synthetic. Several synthetic rubbers or elastomers are used for pharmaceutical components. These are listed in Table 10. However, there is only one type of commercial NR, which is derived from the rubber tree *Hevea Brasiliensis*. "Latex sensitivity" is associated only with NR and not with the synthetics, although other types of allergic reactions can result from contact with synthetic rubbers. NR is processed and used in two forms—liquid or latex rubber and solid or dry rubber, often referred to as crepe, SMR, and SIR. Specific proteins that are contained in both the latex and dry types cause the sensitivity to NR. Thus, the medical community and regulatory authorities have used the term "latex" for both forms of NR when "latex sensitivity" is discussed. Latex reactions reported in the literature have thus far been attributed to contact with components made from liquid rubber but not from dry rubber. Components made from liquid rubber are made by a dipping process that is best suited for thin-walled items such as gloves, condoms, and catheters. None of the typical rubber packaging components shown in Figs. 1 and 2 is made from latex rubber;—they are all made from dry rubber via a molding process. Many studies have been published regarding the allergic

properties of latex and dry rubber (28, 29) and further studies are in progress to determine if exposure to these dry rubber components can cause allergic latex reactions (30).

There is a great deal of regulatory activity in an attempt to protect the public from unexpected latex reactions. In 1996, the USP proposed a change in section <381> that would prohibit the use of NR in elastomeric closures (31); however, it rescinded this change in April 1997, stating that closure manufacturers should instead devise latex protein limits. A test for the water-soluble protein content of elastomers, based on an ASTM test (2), was published as USP <836> but no specifications or limits were proposed (33). At the same time, the FDA published a final rule that made it mandatory to provide labeling statements on medical devices and packaging components that contain NR (34). This rule was later amended to exclude combination drug/device and biologic/device products such as rubber stoppers and plungers for prefilled syringes (35). The uncertainty about the allergic risk from dry NR components and pending regulations have significantly reduced the use of NR in packaging for new drugs and in devices. Substitutes such as isoprene and SBR rubbers are finding increased use.

Preprocessed Components

Preprocessed closures, commonly referred to as RtS or Ready for Sterilization and RtU or Ready for Use, are an unstoppable trend in pharmaceutical packaging. Information on the manufacturing of these products was described previously in this review. The purpose of preprocessed closures is to reduce total processing costs and improve closure characteristics. Typical RtS closure characteristics are as follows:

Endotoxin Level: < 1 EU/closure

Bioburden Level: < 2 cfu/closure

Silicone Level: 10–40 µg/closure

Visible Particulate Matter: < 20 particles in 25 to 50-µ range; < 2 particles in 50 to 100-µ range; < 1 particle over 100 µ.

Coating and Surface Treatments

Although the material science of rubber compounds has greatly improved, drug-closure-interactions and surface lubricity are problematic for packaging engineers. Surface modifications of closures are frequently necessary to meet acceptance standards set by the USP, EP, JP, and ISO as well as the expectations of regulatory authorities. In practice, both liquids and solids are applied to closure surfaces to minimize interactions and improve lubricity.

Table 11 Commercially available coated and surface treated components

Product name	Material	Primary use	% Surface coated	Supplier ^a
Abboclad	Fluorinated polymer solid film	Compatibility	Plug surface	AB
B2	Silicone, polymerized liquid	Lubricity	Top, plug or both surfaces	WP
Coated stopper	Parylene deposited solid film	Compatibility	Total	IT
Deposition coated stopper	Vapor deposition coated solid film	Compatibility	Total	AB
Flurotec	ETFE solid film	Compatibility	Top, plug or both surfaces	WP & DS
Omniflex plus	Solid fluoropolymer coating	Compatibility	Total	HP
R2	Polymer, nonsilicone solid	Lubricity	Total	ST
SAF	Silicone, high viscosity liquid	Lubricity	Total	HP
Slipcoat	Plasma deposited polymer solid	Lubricity	Total	AL

^aSee Table 7 for supplier information.

A compilation of commercially available coated and surface treated components is shown in Table 11 (36). Although these coating and surface treatments may add significantly to the purchase price of closures they often reduce the total drug product cost by providing the following benefits:

- Increased lubricity, which allows faster processing speeds
- Decreased drug–closure interactions, which permits the marketing of some products not compatible with uncoated rubber and better quality and longer shelf life for others
- Decreased particulate matter, which reduces the number of units rejected for visible particulate matter

Container-Closure Seal Integrity

The FDA Guidance on Container Closure Systems (Ref. May 1999 Guidance) lists sterility or container integrity as an important parameter to be considered in the section on Protection. Seal integrity tests can be done by both physical and microbial methods, but historically, sterility testing alone has been used. A 1998 FDA draft guidance discusses the replacement of the sterility test with an appropriate container-closure integrity test in the stability protocol, permitting an alternative to sterility testing for proving the continued capability of containers to maintain sterility (37). Kirsch et al. (38–41) published a series of four papers that studied mass spectrometry-based helium leak detection, microbial ingress, and vacuum decay and the correlation between these methods. The PDA also published an updated technical report that provides guidance for evaluating pharmaceutical package integrity (42), and Guazzo has published an excellent review article that outlines the advantages and limitations of current methods (43).

SUMMARY

Rubber packaging and device components are an important part of the overall medical delivery system. Without innovative packaging systems, modern drugs would not be available today. Advances in drug development have initiated research in new packaging and delivery systems while the availability of innovative packaging has led to the introduction of new drug therapies. Innovation, while containing costs and conforming to regulations, is the challenge for the 21st century.

EFFERVESCENT PHARMACEUTICALS

Nils-Olof Lindberg

Pharmacia AB, Helsingborg, Sweden

Henri Hansson

Galenica AB, Meleon, Malmö, Sweden

INTRODUCTION

Effervescent tablets are uncoated tablets that generally contain acid substances and carbonates or bicarbonates, and that react rapidly in the presence of water by releasing carbon dioxide. They are usually dissolved or dispersed in water before administration (1).

Effervescent mixtures have been known for over 250 years. During the 1930s, the success of Alka Seltzer created a vogue for effervescent products, including tablets (2). Effervescent tablets have been reviewed (3–5).

Effervescent reactions have also been employed in other dosage forms, such as suppositories (laxative effect), vaginal suppositories (mainly contraceptive effect), and drug delivery systems (e.g., floating systems and tablets rapidly dissolving in the saliva).

Effervescent products should be stored in tightly closed containers. Desiccants are usually added to the containers.

PHARMACOPEIAL MONOGRAPHS

Soluble, effervescent tablets are prepared by compression. In addition to active ingredients, they contain mixtures of acids (citric acid, tartaric acid) and sodium bicarbonate (NaHCO_3) that release carbon dioxide when dissolved in water (6). The *United States Pharmacopeia* (USP) 24 includes the following seven monographs: Acetaminophen for Effervescent Oral Solution; Aspirin Effervescent Tablets for Oral Solution; Potassium Bicarbonate Effervescent Tablets for Oral Solution; Potassium Bicarbonate and Potassium Chloride for Effervescent Oral Solution; Potassium Bicarbonate and Potassium Chloride Effervescent Tablets for Oral Solution; Potassium and Sodium Bicarbonates and Citric Acid for Oral Solution; and Potassium Chloride, Potassium Bicarbonate, and Potassium Citrate Effervescent Tablets for Oral Solution (7).

Effervescent tablets as well as effervescent granules and powders are mentioned in the *European Pharmacopoeia*

(Ph. Eur.), although it does not contain any monographs regarding specific drugs (1, 8).

THE EFFERVESCENT REACTION

Acid–base reactions between alkali metal bicarbonate and citric or tartaric acid have been used for many years to produce pharmaceutical preparations that effervesce as soon as water is added. In such systems, it is practically impossible to achieve much more than an atmospheric saturation of the solution with respect to the released carbon dioxide. If the acid dissolves first, then the bulk of the reaction takes place in the saturated solution in close proximity to the undissolved bicarbonate particles. If the bicarbonate dissolves faster, the reaction essentially takes place near the surface of the undissolved acid. Such suspension systems do not favor supersaturation with respect to carbon dioxide because the particulate solids act as nuclei for bubble formations (9).

RAW MATERIALS

General Characteristics

With regard to compressibility and compactibility, the considerations pertaining to raw materials in effervescent products are similar to the ones that prevail in evaluating raw materials intended for conventional tablets. However, poor compactibility cannot usually be compensated for by the use of binders, as this will prevent a rapid dissolution of the effervescent tablet. Addition of a binder is generally not as critical for the dissolution of effervescent granules or powders.

The general tablet compaction process normally is described by a number of sequential phases: rearrangement, deformation (elastic, plastic) of initial particles, fragmentation, and deformation of fragments. Particle surfaces are

brought into close proximity and interparticulate attraction or bonds will be formed (10). Similar conditions will prevail with the effervescent tablets.

A very important property for effervescent products is the adsorption/desorption isotherm of the raw material and, consequently, its moisture content. To avoid a premature effervescent reaction in the tablets, substances with low moisture contents will have to be used. The aqueous solubility is another important property of the substances used in effervescent products. It is also important to use raw materials that are easily wetted. Of course, the taste of the employed substances is important.

Acid Materials

The acidity for the effervescent reaction can be obtained from three main sources: acids, acid anhydrides, and acid salts. Traditional sources of acid materials are the organic acids, citric and tartaric acid; however, some acid salts also are used.

Acids

Citric acid: Citric acid is obtained as a monohydrate or an anhydrate. A variety of particle-size grades are available—colorless, translucent crystals, or white, granular-to-crystalline powder. Citric acid is odorless and has a strong acidic taste. It is soluble in less than 1 part of water and 1 in 1.5 parts of ethanol (11).

Citric acid monohydrate melts at 100°C. It loses water at 75°C, becomes anhydrous at 135°C, and fuses at 153°C. At relative humidities (RH) lower than approximately 65%, it effloresces at 25°C; the anhydrous acid is formed at humidities below approximately 40%. At RH between approximately 65 and 75%, it sorbs insignificant amounts of moisture, but above this, substantial amounts are absorbed (Fig. 1) (11).

Figure 1 also includes the sorption curve of the anhydrate. The anhydrous form melts at 135°C during decomposition (12). At RH approaching 75%, the monohydrate is formed (11).

Information from Heckel plots indicates that anhydrous citric acid is predominantly fragmented during compression (13). The elastic deformation and consequently the elastic recovery during decompression are low (14).

Tartaric acid: Tartaric acid is soluble 1 in 0.75 parts of water, and 1 in 2.5 parts of alcohol (15). It sorbs insignificant amounts of moisture at RH up to approximately 65%, but at RH above approximately 75%, substantial amounts are absorbed (Fig. 1).

Studies indicate that tartaric acid behaves in a manner similar to that of anhydrous citric acid. During compression, the acid fragments predominantly, and the

Fig. 1 Sorption isotherms of some hygroscopic acids. Key: x axis = relative humidity, %; y axis = moisture content, %; ○ = citric acid monohydrate; Δ = anhydrous citric acid; □ = tartaric acid. (Adapted from Ref. 16.)

elastic deformation and consequently the elastic recovery were low (14).

A comparison of the formation of carbon dioxide from effervescent tablets based on anhydrous citric acid, ascorbic acid or tartaric acid, and NaHCO_3 in stoichiometric proportions indicated that ascorbic acid and anhydrous citric acid behaved similarly. However, tartaric acid formed the most carbon dioxide, but the disintegration time was longer (16).

Ascorbic acid: Ascorbic acid occurs as white to light yellow crystalline powder or colorless crystals with a sharp, acidic taste and no odor. It is not hygroscopic. Upon exposure to light, it gradually darkens. Ascorbic acid is soluble 1 in 3.5 parts of water and 1 in 50 parts of ethanol (17).

Ascorbic acid particles show an intermediate fragmentation during compaction. The relatively low tablet strength indicates that the attraction forces are relatively weak and not very resistant to stress relaxation and elastic recovery (18).

Ascorbic acid can be used as the acid source. The speed of release of carbon dioxide from a mixture of ascorbic acid and

NaHCO_3 is comparable with that produced by citric or tartaric acid– NaHCO_3 combinations. Since ascorbic acid is less hygroscopic than citric and tartaric acid, using ascorbic acid as the only acid source makes it possible to produce effervescent tablets in a nonairconditional area (19).

Fumaric acid: Fumaric acid is a white, odorless or nearly odorless crystalline powder. It is soluble 1 in 222 parts of water and 1 in 28 parts of ethanol (20). The sorption isotherm indicates that fumaric acid is not a hygroscopic substance (16).

Acetylsalicylic acid (aspirin): Although acetylsalicylic acid is a drug frequently used in effervescent form, it cannot be used as the acid source because of its low water solubility. Additional acid is necessary to decrease the reaction time.

Other acids: Malic acid is hygroscopic and readily soluble in water. It has been suggested for effervescent products (3).

Other acids have been mentioned in connection with effervescent products (3, 5).

Acid anhydrides: The use of acid anhydrides as the acid precursor has been investigated. However, their use in commercial products is limited.

Acid salts: Amino acid hydrochlorides readily release acid when in solution. However, these materials have the disadvantage of being expensive and rather hygroscopic (4). Other suggested acid sources include: sodium dihydrogen citrate (21), a nonhygroscopic substance (16); disodium hydrogen citrate, which is nonhygroscopic below approximately 93% RH/20°C (16); and sodium acid phosphate, which is very soluble in water.

Sources of Carbon Dioxide

Both carbonates and bicarbonates are used as carbonate sources, but the latter is most often used.

Sodium bicarbonate (NaHCO_3)

NaHCO_3 is an odorless, white crystalline powder with a saline, slightly alkaline taste. A variety of particle-size grades of powders and granules are available. The carbon dioxide yield is approximately 52% by weight. At RH below approximately 80% (at room temperature), the moisture content is less than 1%. Above 85% RH, it rapidly absorbs an excessive amount of water and may start to decompose. Its solubility in water is 1 part in 11 parts at 20°C, and it is practically insoluble in 95% ethanol at 20°C. When heated to 250–300°C, NaHCO_3 decomposes and is converted into anhydrous sodium carbonate. However, this process is both time- and temperature-dependent, commencing at about 50°C. The reaction proceeds via surface-controlled kinetics, and when NaHCO_3 crystals are heated for a short period of

time, very fine needle-shaped crystals of anhydrous sodium carbonate appear on the surface (22).

In humid air, there is a slow decarboxylation of NaHCO_3 , where as sodium sesquicarbonate $\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$ is formed (23).

NaHCO_3 mainly consolidates by plastic deformation and not by fragmentation (18). It is a nonelastic substance (13).

In order to overcome the poor flowability and low compressibility of NaHCO_3 , a spray-drying technique was used. Additives such as polyvinylpyrrolidone and silicon oil were found to be essential to obtain direct compressible spray-dried NaHCO_3 . The product showed good compression characteristics without being transformed into sodium carbonate (24).

Sodium carbonate: Sodium carbonate is commercially available as an anhydrous form and as a monohydrate or a decahydrate. All forms are very soluble in water. The anhydrate is hygroscopic (25).

Potassium bicarbonate: Potassium bicarbonate (KHCO_3) is very soluble in water. When heated to approximately 200°C, it is decomposed, and potassium carbonate, water, and carbon dioxide are formed (26). Consequently, KHCO_3 is less sensitive to heat in connection with drying than is NaHCO_3 . Above approximately 80% RH at 20°C, substantial amounts of water are adsorbed by KHCO_3 .

Potassium carbonate: The moisture scavenging effect of potassium carbonate in effervescent tablets has been investigated (27).

Calcium carbonate: Precipitated calcium carbonate occurs as fine, white, odorless, and tasteless powder or crystals. It is practically insoluble in water and ethanol (95%). Precipitated calcium carbonate is nonhygroscopic (28). Calcium carbonate is a high-density, not very compressible material (29). It is known to consolidate by fragmentation (30).

Other sources: Amino acid–alkali metal carbonate derivatives, such as sodium glycine carbonate, have been suggested as sources of carbon dioxide.

Sodium glycine carbonate is a nonhygroscopic, heat-resistant, stable substance (31). However, the carbon dioxide yield—approximately 18% by weight—is only about one-third of NaHCO_3 .

PRODUCTS

Dosage Forms

Effervescent tablets (1, 6), granules, and powders (8) are mentioned in the pharmacopoeias and exist as products

on the market. The effervescent tablet provides several advantages over conventional oral solid dosage forms. It is administered as a reasonably palatable, sparkling solution. Consequently, it can be given to patients who have difficulties swallowing capsules or tablets. Since the drug is administered as a solution, problems associated with dissolution, that is, absorption rate and extent of bioavailability, are avoided. Drugs that are unstable when stored in aqueous solutions are more often stable in the effervescent tablet.

Effervescent dosage forms have several drawbacks when compared with aqueous solutions and plain tablets. For example, they are relatively expensive to produce due to the use of large amounts of more or less expensive excipients and the necessary special production facilities, as well as high Na^+ and/or K^+ concentrations. In addition, when compared with plain tablets, effervescent tablets are bulky, even though small packages that are easy to carry in a pocket or handbag are available. Finally, it is sometimes difficult to make unpleasant tasting drugs sufficiently palatable in an effervescent form.

When an effervescent product is dropped into a glass of water, the reaction between the acid and the NaHCO_3 is quite rapid, usually completed within 1 minute or less (32). The effervescent reaction is also used in other pharmaceutical dosage forms than the traditional effervescent products. Effervescent laxative suppositories that release carbon dioxide have been thoroughly studied (33). One product has been on the Swedish market for many years. Effervescent vaginal suppositories are described (34). Pulsatile and gastric floating drug delivery systems for oral administration based on a reservoir system consisting of a drug-containing effervescent core and a polymeric coating also have been investigated (35).

Drugs (Product Categories)

Many drugs and drug compositions have been used for effervescent products. Some of these are listed below.

Acetylsalicylic acid (aspirin) is a common drug in many different effervescent products (36, 37).

Paracetamol (acetaminophen) is another analgesic used in effervescent preparations (38).

Effervescent compositions of ibuprofen, another analgesic, are marketed.

Among effervescent antacid preparations, Alka-Seltzer, an effervescent antacid analgesic product, has been available since the 1930s. Pure effervescent antacid products are marketed in many countries.

Effervescent tablets of ascorbic acid, 0.5–1 g, are well known. Other vitamins as well as calcium and some minerals have also been included.

Acetylcysteine, a mucolytic agent that also is used as an antidote for paracetamol overdose, is available as an effervescent tablet.

Effervescent products of water-insoluble drugs have been manufactured. A successful example is the effervescent activated charcoal preparation suggested in the management of theophylline poisoning (39).

Electrolyte Balance Considerations

Effervescent tablets normally have a high sodium content. In most of the effervescent analgesic products in Sweden, the sodium content is approximately 15 mmol. This sodium content may be contraindicated in some patients (e.g., in patients with active sodium-retaining status such as congestive heart failure or renal insufficiency). Otherwise, there are no restrictions concerning the sodium content of effervescent tablets.

Biopharmaceutical Aspects

Drugs are most rapidly absorbed from the gastrointestinal (GI) tract when administered as aqueous solutions. Although dilution of the drug solution in the gastric fluids sometimes results in precipitation, the extremely fine nature of the precipitate permits rapid redissolution (40). The rapid absorption of the aqueous solution is the idea behind effervescent analgesic products, for example. Furthermore, consistent absorption is expected with the solution, as disintegration and dissolution in the GI tract are bypassed.

Effervescence may produce physiological changes within the body. Carbon dioxide bubbling directly onto the intestinal epithelium induced enhanced drug permeability due to an alteration of the paracellular pathway. This, in addition to fluid flow and membrane hydrophobicity concepts, may account for observed increases in drug flux (41).

Buffered effervescent aspirin tablets are generally believed to have a less irritant effect on the gastric mucosa and cause less GI blood loss than conventional tablets. This view has been questioned.

The bioavailability of acetylsalicylic acid from three different dosage forms—two types of effervescent tablets with different buffering properties and tablets of a conventional type—was studied in healthy volunteers. Complete absorption was found for all the preparations

studied. Both effervescent tablets were rapidly absorbed. The buffering properties did not influence the rate of absorption (36).

Effervescent aspirin, soluble aspirin, and soluble aspirin to which sufficient NaHCO_3 had been added to give it the same buffering capacity as the effervescent preparation, were compared in healthy volunteers. There were no significant differences in plasma salicylate levels at any time after taking these preparations (37).

The absorption of the effervescent formulation of paracetamol was compared with that of a plain tablet in normal volunteers. As to the rate of absorption, this was more rapid and consistent from the effervescent preparation than from the plain tablet. This may have important therapeutic implications where a rapid and predictable analgesic effect may be desired (38).

The bioavailability of an effervescent ibuprofen tablet was compared to a sugar-coated tablet. Ibuprofen was absorbed more rapidly from the effervescent tablet but both formulations were bioequivalent in respect to peak plasma concentrations and area under the plasma concentration curves (42).

PROCESSING

Environment

The manufacturing of effervescent tablets requires careful control of environmental factors. As early as the 1930s, it was clear that it was essential to maintain RH throughout the plant of no more than 20%. In addition, a uniform temperature of 21°C also was desirable (2).

A maximum of 25% RH at a controlled room temperature of 25°C or less is usually sufficient to avoid problems caused by atmospheric moisture (3).

Equipment

Conventional processing equipment (mixers, granulators, roller compactors, drying equipment, and mills) can be used to produce effervescent preparations if the influence of atmospheric moisture is considered. As a rule, tablet presses have to be adapted to handle effervescent products, except for tablets with a sufficient proportion of a self-lubricating substance, such as acetylsalicylic acid.

Wet Granulation Methods

The acid and carbonate parts of the effervescent formulation can be granulated either separately or as a

mixture with water (crystal water of citric acid, liquid water, or water vapor), ethanol (possibly diluted with water), isopropanol, or other solvents.

When granulating with solvents without any moisture, no effervescent reaction will occur provided the raw materials are dry and the process is performed in a low humidity atmosphere. However, citric acid will partly dissolve in ethanol or isopropanol, and function as a binder when the solvent is evaporated.

When granulating either with solvents containing water or pure water, the effervescent reaction will start. Care must be taken to maintain adequate control of the process. Vacuum processing is often beneficial due to the ability to control the effervescent reaction and the drying process.

In the fusion method of granulation, the effervescent mixture is heated to approximately 100°C (the melting point of the monohydrate) so that the water of crystallization from hydrous citric acid is released. This process is sporadic and difficult to control, especially in a static bed (3).

By means of high-shear mixers and the heat generated during mixing, it was possible to prepare granular effervescent products in batch sizes of 60–300 kg using the fusion method (43).

Citric acid is moistened and added to the NaHCO_3 . Partial wet fusion occurs, and granules are formed by kneading in a suitable mixer. The granules are tableted while still damp, with the moist citric acid acting as a lubricant. The compressed tablets are transferred immediately and continuously to ovens where they are dried at 70–75°C. Drying also hardens them. As soon as they leave the dryer, the tablets are packed in aluminum foil lined with polyethylene (44).

X-ray diffractometry and infrared (IR) spectrophotometry were used to study the reaction between citric acid and NaHCO_3 when granulating the mixture with water in a high-shear mixer and vacuum drying the wet mass. The contact time before drying varied as did the water content. At low water levels, varying the contact times did not change the citric acid. However, with higher levels of water content, the presence of monocitrates, dicitrates, and tricitrates was verified. The loss of carbon dioxide during granulation occurred in the presence of, especially, dicitrates and tricitrates (45).

Effervescent granules were prepared in a fluid bed granulator/dryer (46).

The drug can be mixed with the effervescent granulate and other excipients or be a part of the granulation. When mixing low proportions of drug with granulate, the risk of segregation must be taken into account.

Dry Granulation

Granulation by slugging (slugs or large tablets that are compressed using heavy-duty tableting equipment) or roller compaction is suitable for materials that cannot be wet granulated. The slugs and the material from the roller compactor are reduced to the proper size. Lubrication is often necessary during slugging but not always with roller compaction. The acidic and basic components may be dry granulated separately or together.

Direct Compression

Some effervescent tablet products are successfully produced by direct compression (e.g., acetylsalicylic acid products). Direct compression normally requires careful selection of raw materials to achieve a free-flowing, nonsegregating, compressible mixture. Effervescent products present the same problems as conventional products in direct compression.

Tableting

The adaptation of a single-punch tablet press for compressing effervescent tablets via external lubrication has been described (5, 47). Only rotary presses are normally used in connection with the commercial production of effervescent tablets. Tablet machine manufacturers have applied various adaptations to their existing equipment to avoid problems due to internal lubrication and punch adhesion. Consequently, many effervescent tablets are produced on rotary presses with external lubrication. Liquid or solid lubricants can be used.

FORMULATION

Excipients (Including Sweeteners and Flavors)

Lubricants

A perfect lubricant (or auxiliary agent, in general) for effervescent products must be nontoxic, tasteless, and water-soluble. Very few traditional lubricants fulfill these requirements.

Intrinsic lubricants are added to the powder mixture and consequently included in the formulation. When added in solid form, the lubricant will have to be finely divided.

Metal stearates, such as magnesium or calcium stearate that serve as lubricants in conventional tablets, are seldom used as intrinsic lubricants in connection with

effervescent tablets due to their insolubility in water. Use of stearates results in an undissolved, foamy, soapy-tasting layer on the surface of the cloudy solution. In addition, normal lubricant concentrations of metal stearates make the tablets hydrophobic, which entails a slow dissolution of the effervescent tablet in the water. However, very low concentrations of metal stearates can be used to improve the rate of solution of effervescent tablets as the tablet will remain immersed in the water during dissolution and not float to the surface the way a tablet without metal stearate would. A floating tablet presents a smaller surface area to the water than a tablet immersed in the liquid.

Sodium stearate and sodium oleate are water-soluble in low concentrations. They have the characteristic soapy taste, which virtually precludes their use in effervescent products.

A combination of 4% polyethylene glycol (PEG) 6000 and 0.1% sodium stearyl fumarate proved to be a good lubricant for ascorbic acid tablets made by direct compression on a small scale (48). Sodium chloride, sodium acetate, and D,L-leucine (water-soluble lubricants) also have been suggested for effervescent tablets (44).

Twenty lubricants for effervescent tablets were tested for lubrication efficiency in direct compression of a standard effervescent formulation. The lubricant concentration was high as compared to traditional tablet lubricants. By increasing the lubricant concentration and the compression force, most lubricants became more effective. The lubricant used in effervescent formulations should combine hydrophobic and hydrophilic properties in order to achieve both good lubrication and a short disintegration time. A medium polar lubricant was the best compromise. Fumaric acid was chosen and its concentration optimized (49). Other research that studied the lubrication of effervescent products indicated optimal concentrations of spray-dried L-leucine and PEG 6000 at levels of 2 and 3%, respectively (50).

Surfactants such as sodium lauryl sulfate and magnesium lauryl sulfate also act as lubricants.

Extrinsic lubrication is provided via mechanisms that apply a lubricating substance, normally paraffin oil, to the tableting tool surface during processing. One method makes use of an oiled felt washer attached to the lower punch below the tip. This washer wipes the die cavity with each tablet ejection. To avoid having tablets stick to the punch faces, materials such as polytetrafluorethylene or polyurethane have been applied to the faces. Another lubrication method sprays a thin layer of lubricant (either liquid or solid lubricant) onto the tool surfaces after one tablet is ejected and before the granulate of the next tablet enters the die cavity.

Products containing acetylsalicylic acid do not usually require additional lubrication.

Glidants

Glidants are usually not necessary. Free-flowing granules, ingredients of appropriate physical form for direct compression, and the large tablet diameters make it possible to exclude the use of glidants.

Antiadherents

The adherence of the granulate or powder mixture to the punch surfaces, so-called picking, can be eliminated by using discs, such as polytetrafluorethylene or polyurethane, cemented to the punch surfaces.

Binders

Binders are commonly used when making conventional tablets. The binders are either added in dry form or dissolved in a suitable solvent and then added in connection with a wet-granulation process. Most binders are polymers and increase the plastic deformation of the formulation.

The use of binders will normally prevent a rapid dissolution of the effervescent tablet. Therefore, many effervescent tablets are formulated without any binder. However, effervescent granules may be formulated with binders since their large surface area, when compared with that of the conventional or the effervescent tablet, will result in rapid dissolution. An effervescent granulation composed of anhydrous citric acid and NaHCO_3 was made with dehydrated alcohol as the granulating liquid. A portion of the citric acid dissolved during the massing and functioned as a binder (51).

In order to compress ascorbic acid from a combination with NaHCO_3 , granulation was required. Common water-soluble binders, such as polyvinylpyrrolidone (polyvidone) or polyvinylpyrrolidone–poly(vinyl acetate)-copolymer, led to a change of color on the part of the ascorbic acid granules. Hydrogenated maltodextrins containing high amounts of maltitol were chosen from a wide range of dextrins and maltodextrins as possible binders. Maltitol was a suitable binder for ascorbic acid effervescent tablets. Formation of crystal bridges of maltitol was the assumed binding mechanism (19). PEG 6000 functions both as a binder and as a lubricant.

Disintegrants or dissolution aids

Disintegrants, which are used in conventional tablets, are not normally used in effervescent tablets because one of the marketing demands is that a clear solution should be obtained within a few minutes after adding the tablet to a glass of cold water.

Diluents

Effervescent products generally do not require diluents. The effervescent materials themselves will have to be added in large quantities.

Sweeteners

Sucrose and other natural sweeteners, such as sorbitol, can be used in effervescent products, although artificial sweetening agents are customary. However, the application of artificial sweeteners is restricted by health regulations. Therefore, the use of such sweeteners will vary from one country to the next based on national standards.

Saccharin or its sodium and calcium salts are used as sweeteners. Aspartame is also employed as a sweetener in effervescent tablets. Earlier, cyclamates and cyclamic acid were the artificial sweeteners of choice, but their use has now been restricted.

Flavors

The simple use of sweetening agents may not be sufficient to render palatable a product containing a drug with an unpleasant taste. Therefore, a flavoring agent can be included. Various dry flavors are available from suppliers. The flavors used must be water-soluble or water-dispersible.

Colors

Water-soluble colors may be added; however, some dyes change color according to pH variations, a consideration that must be noted before a dye is selected.

Surfactants

This type of excipient is sometimes used to increase the wetting and dissolution rate of drugs. Attention must be paid to the formation of foam.

Antifoaming agents

To reduce the formation of foam, and consequently the tendency of drugs to stick to the wall of the glass above the water level, an antifoaming agent, such as polydimethylsiloxane, can be used. However, antifoaming agents do not normally form constituents of effervescent products.

Formulations (Including Optimization)

Literature on formulations of effervescent products is relatively sparse. Table 1 presents some examples of effervescent products on the Nordic market.

A fractional factorial design was employed in the preparation of effervescent aspirin tablets. The optimum conditions for preparing the tablets were determined following the path of steepest ascent (53).

Table 1 Some compositions of effervescent tablets on the Nordic market: Components and weight per tablet

	Product A		Product B		Product C	
	Component	mg	Component	mg	Component	mg
Drugs	Ascorbic acid	1000	Acetylsalicylic acid	500	Paracetamol	500
Excipients			Caffeine	50		
	Citric acid, anhydrous	700	Citric acid, anhydrous	500	Citric acid, anhydrous	1200
	Sodium bicarbonate	490	Sodium bicarbonate	1250	Sodium bicarbonate	1550
	Polyethylene glycol 6000	45	Docusate sodium	0.85	Polyvidone	25
			Sodium benzoate	0.15	Sodium cyclamate	45
	Sorbitol	25			Saccharin sodium	5
	Saccharin sodium	12			Lemon flavor	25
	Riboflavin sodium phosphate (for color)	1			Magnesium stearate	1.4
	Orange flavor	2				

(Adapted from Ref. 52.)

An experiment investigating the effects of tablet manufacturing conditions, tablet formulations, tablet compression pressures, storage conditions, and storage times was performed on five different formulations (54). The effects of two formulation factors (the ratio of citric acid/ NaHCO_3 and the polyvidone content) and two process factors (the temperature and the velocity of the fluidizing air) on granule size, powder content, and dissolution rate of the tablets were studied using factorial design. In addition, the levels of the significant factors were optimized with the path of steepest ascent (46).

Solid dispersions of poorly water-soluble drugs were made by the fusion method. Citric acid was employed in various ratios with NaHCO_3 as the carrier for these drugs (55).

Stability

The greatest problem with effervescent products is the loss of reactivity with time if exposed prematurely to moisture (i.e., the stability of the effervescent system). In addition, the stability of the drug and some excipients, such as flavors, also must be considered.

Effervescent products are not stable in the presence of moisture. Most effervescent products are hygroscopic and can therefore adsorb enough moisture to initiate degradation if they are not suitably packaged.

Tablets made with equivalent amounts of NaHCO_3 and tartaric acid were stored at 70°C . In a closed system, a reaction between the NaHCO_3 and the tartaric acid occurred. When the tablets were stored as an open system,

the weight loss was concluded to be a decarboxylation of the NaHCO_3 (56).

Effervescent compositions may be markedly stabilized if the NaHCO_3 is partly converted to the corresponding carbonate. Usually, the desired degree of stability is attained if approximately 2–10% of the weight of the bicarbonate is converted to the carbonate (57). The addition of sodium carbonate did not by itself improve stability. One explanation for the stabilizing effect caused by heating of the bicarbonate could be that heating causes a uniform distribution of the carbonate on the surface of the bicarbonate so that the water-scavenging efficiency is greater. Another explanation is that the carbonate formed by the rupture of the bicarbonate crystals would be much finer than added crystalline sodium carbonate, however finely ground. A third explanation is the possibility that double salts might be present and that they could be better scavengers than the carbonate itself (56). The moisture scavenging effect of potassium carbonate was determined and the concentration optimized for a specific formulation (27).

The stability of three commercial effervescent and one dispersible aspirin tablet were evaluated by factorially designed experiments. Temperature affected the hydrolysis of all tablets, whereas humidity influenced one product in a plastic tube and one in an aluminum tube (58).

Mercury-intrusion porosimetry and a cantilever beam-proximity transducer balance were used to monitor the stability of selected effervescent tablet systems. An index of reactivity was obtained from the balance measurements. The porosity measurements proved to be useful in elucidating tablet-pore structure changes over time.

Compression pressure and manufacturing conditions were not significant factors in the stability of an effervescent system when nonhygroscopic materials were used (54).

Codeine phosphate in a paracetamol-codeine effervescent tablet was found to react at room temperature with the citric acid constituents to form citrate esters of codeine. The esterification was confirmed in a solid-state reaction at an elevated temperature. Tartaric acid also yielded an ester with codeine phosphate in a similar nonsolvolytic reaction (59).

PRODUCTION

Granulation

At the Pharmacia plant in Helsingborg, Sweden, approximately 1200 kg of effervescent granulate is produced daily. Anhydrous citric acid and NaHCO_3 are massed with ethanol in a planetary mixer and the wet mass is dried on trays. Additional effervescent granulates are produced with vacuum equipment (Topo granulator) where water is the main component of the granulation liquid. The Topo granulator, developed for preparation of granules and coated particles in a vacuum, handles the mixing, granulation, drying, and milling/sieving as a closed system.

The fusion method, which employs heat to liberate water of crystallization from hydrous citric acid in order to effect moistening, was applied by using a high-shear mixer to generate heat (43). Batch sizes of 60 and 300 kg were granulated.

Anhydrous citric acid and NaHCO_3 were granulated with ethanol in a twin-screw extruder at powder flow rates of 60–90 kg/h in a continuous process (51).

The air suspension coating–reacting technique also is used in the production of effervescent granulates.

Tableting

Effervescent tablets are normally produced by machines with external lubrication systems. Most tablet machine manufacturers can add this type of equipment to their rotary machines. Products with a high proportion of acetylsalicylic acid can be manufactured without any traditional lubricants. Consequently, conventional rotary tablet presses can be used. Effervescent acetylsalicylic acid tablets are produced on ordinary high-speed rotary presses at the Pharmacia plant in Helsingborg, Sweden.

Effervescent granules can be tableted while still damp since moist citric acid acts as a lubricant. The compressed

tablets are transferred immediately and continuously to ovens where they are dried. Drying also hardens them (44).

Several types of steel are normally used in the manufacture of compression tooling. Material rich in nickel was found to have the best resistance to rusting induced by a hydrochloride salt, although other factors, such as humidity, temperature, and contact time, also were responsible for the rusting of tooling material (60). This information may be useful when ordering and managing tooling materials for effervescent tablets.

The compression of effervescent mixtures usually results in severe picking and sticking. By means of flat-faced punches with discs of polytetrafluorethylene, the sticking to tablet-punch surfaces is overcome (61). Other nonadherent materials, such as Vulkollan® (a polyethane), Hostalit® (polyvinyl chloride), and Resopal® (a melamine), have been used (62). The disc of the plastic material is attached to the recess of the punch surface by glue or adhesive tape. It should be noted that fragments of the polymer can rub off during compression.

Effervescent tablets were produced using four different formulations that contained citric and/or tartaric acid and NaHCO_3 with polyvidone and PEG 6000. The adhesion of each formulation to the metal faces of the punch tips was determined by means of electron microscopy, surface-roughness measurements, and quantification of punch-weight variations during tablet production. The basic formulations were inherently adhesive and produced tablets with a weak, porous structure; the tablets were rougher than conventional, noneffervescent compressed tablets. Both formulations that contained tartaric acid produced tablets with a lower surface roughness and had less of a tendency to stick to tablet-punch faces than the two formulations that contained citric acid alone. The addition of a water-soluble sucrose ester had a beneficial effect, especially on formulations with inherently high adhesive tendencies (63).

In-Process Quality Control

For a rapid determination of loss on drying, an IR drying balance may be used. In the matter of size distribution, effervescent granulations are controlled by sieve analysis.

During the compression of effervescent tablets, in-process tests are routinely run to monitor the process. These tests include controls of tablet weight, weight variation, thickness, crushing strength, disintegration, and appearance of the tablet. Friability and pH of the solution may be additionally tested. Electronic devices that monitor tablet weight are normally used.

Inspection of the punches is carried out during the manufacturing of the tablets when plastic insertions are used. Inspections ensure that the plastic insertions are intact, i.e., that no loss or damage to the discs has occurred.

Product Evaluations

Both chemical and physical properties have to be considered when evaluating effervescent products. In this review, only the physical properties will be discussed, except where the chemical characteristics are especially influenced by the effervescent base. For more detail, Ph. Eur. includes a special disintegration test for effervescent tablets (1) and granules (8).

Many tests (e.g., titrimetric, gravimetric, colorimetric, and volumetric tests as well as loss-of-weight measurements and pressure measurements) have been proposed in order to determine carbon dioxide content (16, 48, 64). Methods based on monitoring carbon dioxide pressure generation and weight loss have been applied (16, 65).

Results from weight-loss measurements were modeled (65). Research indicates that the determination of water content by Karl Fischer analysis in effervescent tablets was possible after extraction with dioxane (66). NaHCO_3 , which reacts with the Karl Fischer reagent, is insoluble in dioxane and does not interfere during the determination.

Near IR (NIR) is a quick and nondestructive method for the determination of water in effervescent products. In addition, it is suitable for in-process quality control. Measurement of pH of the solution is often performed. The conditions are important for congruent results.

Tablets

The disintegration and dissolution times are very important characteristics of effervescent products. A well-formulated effervescent tablet will disintegrate and dissolve within 1–2 min to form a clear solution. Consequently, the residue of undissolved drug must be minimal. The temperature of the water influences the dissolution time. It is, therefore, important to choose a water temperature that is actually used by consumers (e.g., cold tap water). Ph. Eur. includes a general requirement on disintegration time of 5 min in water 15–25°C (1).

Factors such as crushing strength and friability will influence the possibility of packaging the tablets on packaging lines, as effervescent tablets chip easily at

the edges during handling. When the tablets are filled in tubes, the tablet height is of the utmost importance since the looseness or tightness of the packaging depends on the tablet height. When small or fairly small amounts of drug form part of the formulation, it is essential that content uniformity be carefully supervised.

Powders and Granules

Disintegration and dissolution time is an important characteristic, as is powder weight variation. The Ph. Eur. requirement time for disintegration of granules is 5 min (8).

Production Area

As the mass of an effervescent tablet is, as a rule, many times larger than that of a conventional tablet, larger amounts of raw material will have to be handled when packaging the same number of tablets. Therefore, the production area will be larger, too, unless a compact continuous line has been constructed.

At the Pharmacia plant in Helsingborg, Sweden, all steps during the production of effervescent tablets (i.e., mixing, granulating, drying, milling, final mixing of granulate and other constituents, tableting, and packaging) are performed in dehumidified areas of <25% RH and <25°C. Other companies perform mixing, granulating, drying, and milling at normal humidities but store the final mixture in dehumidified areas while slowly bubbling dehumidified air through the mixture. The mixture is then tableted and packaged in a small, dehumidified area around the tablet and packaging machine.

In direct compression, the mixing can be performed at normal humidities; however, in that case, the mixture is dried (to prevent a premature effervescent reaction) by means of causing dehumidified air to flow through the bed in a suitable container. Tableting and packaging are also performed in the dehumidified area. Thus, the number of manufacturing stages in the low humidity zone is reduced.

PACKAGING

Effervescent tablets should be stored in tightly closed containers or moisture-proof packs (6).

Even the moisture in the air may be enough to initiate the effervescent reaction of an effervescent product if it is not properly protected. When the consumer opens the

container, the effervescent product will again be exposed to the moisture in the air. Consequently, the packaging of all effervescent products is very important. The time between tablet production and start of packaging operation should be kept as short as possible.

Ph. Eur. recommends that effervescent granules and powders be stored in airtight containers (8). In the past, acidic and alkaline components were wrapped separately to prevent effervescent reactions during the storage of powders and granules.

Materials

Effervescent products are usually packed in individual aluminum foil pouches and effervescent tablets are often packed in metal tubes. To avoid excessive laminate stress, the dimensions of the sachets should be adapted to the dimensions of the tablet or the amount of granulate. These pouches are arranged in conveniently sized strips and stacked in a paperboard box.

The metal tube is a multiple-use container sealed with a moisture-proof closure. The tablets are stacked on top of one another. Consequently, a minimum of air surrounds them. The tubes are seamless, extruded aluminum packages. They are closed by tightly fitting plastic snap caps that contain a desiccant chamber. Tubes of plastic materials, such as polyvinyl chloride or polypropylene, have been tested with effervescent tablets. Acceptable stability was obtained with some of these products. Plastic tubes are used more often due to their lower cost and lower noise level during the packaging operation.

Aluminum-foil blisters can provide hermetic packs. Similar protection can be achieved by using a foil-bearing laminate or a strip pack. A special strip pack for effervescent tablets, where each tablet is connected to a desiccant via a channel, has been suggested (67).

The effect of environmental moisture on the physical stability of effervescent tablets in foil-laminate packages containing microscopic imperfections was examined. Physical stability, after storing at different RH and temperature conditions, was assessed by noting whether the tablet components reacted prematurely. A penetrating dye-solution test was used in order to determine whether the foil packages permitted any transmission of moisture. High humidity accelerated the physical deterioration of effervescent tablets when stored in packets of poor integrity (68).

Filling

Packaging operations must be conducted in a low humidity environment if the long-term stability of the product is to

be maintained. The tablets must be hard enough so as not to break during packaging.

Quality Control

Individual foil packets are tested for proper sealing. Several methods of rapid seal integrity testing have been devised, such as the vacuum underwater method, detection of tracer material sealed within the pouch, purging with detectable gas, IR seal inspection, and electronic air-tightness testers (3).

CONCLUSION

The traditional effervescent product is dissolved prior to oral intake. This requires the drug to have an acceptable taste. Since the drug is given as a solution, the absorption is normally rapid and the bioavailability is usually good.

The commercial manufacturing of effervescent products involves controlling air humidity in the production area. Special tablet machines are generally required, and the package is a very important part of the effervescent product. Over-the-counter analgesics have been very successful as effervescent tablets on certain markets.

ACKNOWLEDGMENT

We are indebted to Ms. Margareta Duberg, Diabact AB, Uppsala for her valuable contribution.

EXCIPIENTS FOR PHARMACEUTICAL DOSAGE FORMS

Patrick J. Crowley

Luigi G. Martini

GlaxoSmithKline, Harlow, United Kingdom

INTRODUCTION

Medicinal dosage forms, regardless of composition or mode of use, must meet the following requirements that underpin efficacy, safety, and quality:

1. Contain an accurate dose
2. Be convenient to take or administer
3. Provide the drug in a form for absorption or other delivery to the target
4. Retain quality throughout the shelf life and usage period
5. Be manufactured by a process that does not compromise performance and that is reproducible and economical.

Few if any active pharmaceutical ingredients have properties that allow incorporation in units that meet all these criteria. Therefore, it is necessary to add other materials to make good any shortfalls. Consequently, virtually every medicinal product is a combination of the drug substance and excipients. These are indispensable components of medicinal products and, in most cases comprise the greatest proportion of the dosage unit. It goes without saying that knowledge of the composition, function, and behavior of excipients is a prerequisite to the successful design, development and manufacture of pharmaceutical dosage forms.

The requirements listed above can be considered the prime reasons for including excipients in dosage forms since they relate directly to product performance. Issues such as regulatory acceptability, environmental effects and impact on cost of the product are also important selection criteria.

A single chapter cannot do justice to the richness and complexity of the possibilities and constraints associated with using excipients to transform a drug to a dosage form. Each topic merits a chapter, possibly a complete volume in its own right. This chapter provides a general overview of the issues involved in selecting and evaluating excipients. More detailed accounts of individual applications, performance, and associated issues may be found in the references.

ACCURACY OF DOSE

Where the active ingredient is very potent (i.e., dose is low), it may be necessary to disperse the drug in a “diluent” or bulking agent. Otherwise, quantities being filled into capsules or dies for tableting may be so low that normal filling and other process variations translate to excessive variation in unit drug content. Likewise, low-dose medications for inhalation as dry powders may have the drug dispersed in or otherwise associated with an inert “carrier” or flow aid. For a diluent to function in this way it must form a homogenous blend with the drug. Otherwise accuracy of dose cannot be guaranteed (1).

Water may be considered a “diluent” in liquid presentations as it provides the required dose in a volume that can be accurately dispensed or administered. It is also invariably present in medications for topical or transdermal application. Water can be one of the most problematic companion materials in a dosage form because of its capability to promote hydrolysis, act as a vehicle for other molecular interactions, or simply be a medium for microbial growth. Such properties illustrate how a material that resolves one problem may pose others that in turn require the presence of additional excipients.

Liquid or semisolid preparations may require the presence of ancillary excipients to effect solvation or dispersion of the active ingredient. In particular, formulations containing drugs in the suspended state may require viscosity-enhancing agents or other additives to ensure that the drug remains homogeneously dispersed. Otherwise, the accuracy of the dose may be compromised.

USER OR PATIENT CONVENIENCE

Drugs that are bitter or otherwise unpalatable, and administered as oral liquids may be unacceptable, particularly to younger patients. Compliance and therefore efficacy may be compromised unless the product can be made more palatable. Thus, sweeteners, flavors, or

taste-masking agents may be present in liquid oral products, in chewable dosage forms, and in effervescent or dispersible tablets that are constituted as liquids prior to use (2).

Some drugs given by injection cause local pain due to high volume, tonicity, pH, etc. An additive that evinces a local anesthetic effect may relieve such discomfort. Benzyl alcohol is employed for this purpose.

RELEASE OF DRUG FROM THE DOSAGE FORM

Once a medication is ingested, applied to a target area, or otherwise administered, the drug must leave the dosage form for absorption or other delivery to the target. This may involve the following:

1. Dissolution in the gastrointestinal (GI) tract following oral dosage;
2. Partitioning to the skin in the case of topical or transdermal preparations;
3. Passage to pulmonary or nasal cavities (inhalation products).

Excipients can ensure that such delivery is expeditious and consistent. Their presence may be even more crucial with more esoteric forms that must be delivered to a tissue, organ, or even specific cells. Researchers are developing excipients that act as “homing devices” to guide drugs to designated targets. Such approaches will be discussed later in this chapter.

In its simplest form, designing “release” into a dosage form involves adding a disintegrant to the tablet or capsule formulation so that on ingestion the compact breaks up and drug is released for dissolution and absorption. In the case of hydrophobic drugs, dissolution may be aided by wetting agents. More complex release patterns involve using excipients to modify release from the dosage form to delay onset of action or otherwise modify the pharmacokinetics of the drug, thereby maximizing efficacy or minimizing side effects.

Excipients can influence delivery from topical and transdermal medications. The propensity of the drug to migrate from the formulation to the application surface is affected by factors such as lipophilicity of the vehicle, drug solubility in the formulation, and effects of additives on the barrier properties of the skin or mucosal surface.

ORAL ABSORPTION ENHANCEMENT

Oral absorption is indirectly aided by excipients that promote release of drug from the dosage form, or help

dispersion and dissolution prior to passage to the systemic circulation. Excipients that promote absorption per se are less widely used. However, lipids have been used to enhance absorption of hydrophobic active ingredients. Dissolution or dispersion of drug in such materials provides a substrate for lipolysis, resulting in an emulsion of drug and lipid that provides enhanced surface area for dissolution and absorption (3).

Lipids such as oleic acid or its salts are reported to slow gastric emptying and also act as an “ileal brake.” This allows longer time for dissolution and absorption in the small intestine (4, 5). Citric acid and other organic acids also have been shown to slow gastric emptying (6). However, the levels required for such effects may be impractical for most dosage forms.

The small intestine is drained by the hepatic portal vein, making the liver the first “port of call” for orally absorbed drugs. Therefore, high hepatic metabolism will compromise systemic availability. Formulation to enhance lymphatic absorption offers the potential for avoiding such first-pass metabolism. It could also target anticancer agents to lymphatic carcinomas (7). Table 1 lists various materials and associated therapeutic agents that have been formulated for lymphatic delivery.

Oleic acid has been used in a novel approach to boost the bioavailability of propranolol (Fig. 1). The effect was ascribed to preferential uptake by the lymphatic system and avoidance of the extensive first-pass metabolism that would follow passage through the hepatic portal system (8). Formulation with triglycerides also enhanced lymphatic absorption of the antimalarial drug halofantrine (9). However, the low lymph/blood flow ratio limits lymphatic absorption to drugs that are highly lipophilic ($\log P > 5$) and that have significant solubility in long-chain triglycerides (>50 mg/mL).

Strategies to breach physical and enzymatic barriers in the intestinal epithelium that hinder passage to the systemic circulation have included enhancing paracellular flux by disrupting “tight junctions” (10, 11). Inhibition of the P-glycoprotein (PGP) that ejects unrecognized or unwanted materials also has been studied (12). Certain lipids are reported to be PGP inhibitors but there are no reports of successful application to commercial products or use in clinical trials.

Yet another approach to intestinal absorption enhancement concerns the inhibition of intestinal Cytochrome P450 3A4, an enzyme responsible for the prehepatic metabolism of many drugs. Grapefruit juice is reported to be a powerful inhibitor of this enzyme and is known to enhance the bioavailability of cyclosporin, triazolam, nifedipine, and other drugs. Studies have been carried out to identify the components in grapefruit juice that evince

Table 1 Drug carriers for lymphatic targeting

Lymphotropic carrier	Drug	Type of interaction
Dextran sulphate	Bleomycin	Ion-pair
Dextran	Mitomycin C	Covalent binding
β -Cyclodextrin oligomer	1-Hexylcarbamoyl-5-fluorouracil	Hydrophobic inclusion
L-Lactic acid oligomer microsphere	Aclarubicin, cisplatin	Incorporation
Gelatin microsphere	Mitomycin C	Incorporation
Intrinsic protein complex	Vitamin B ₁₂	Complex
Styrene-maleic acid anhydride-co-polymer	Neocartinstation	Covalent binding
Liposome	Ara-C	Encapsulation
S/O emulsion	5-Fluorouracil, Bleomycin	Encapsulation
Lipid mixed micelle	Interferon, TNF	Hydrophobic binding
Chylomicron, LDL	Cyclosporine, vitamin A, coenzyme Q, DDT	Incorporation
Carbon colloid	Ethinylesteradiol 3-cyclopententyl ether Mitomycin C, Aclarubicin	Hydrophobic adsorption

(From Ref. 7.)

this effect (13, 14). It could be argued that inclusion of such materials (thought to be flavinoids), as “excipients” in the dosage form would lead to not only more complete but also more consistent systemic levels by counteracting inconsistencies brought about by enzyme inhibitors in food and drink (such as grapefruit juice). Time will tell whether the ongoing interest in this area will lead to new “excipients” that modulate absorption in this way.

Excipients that are bioadhesive or that swell on hydration can promote absorption by increased contact with epithelial surfaces, by prolonging residence time in the stomach, or by delaying intestinal transit. Cellulose ethers, gums of natural origin, and synthetic acrylic acid polymers have been evaluated for such purposes. The range of materials available and their differing viscoelastic and rheological behaviors mean that it is possible, by

judicious admixture, to develop delivery units with balanced properties so that adhesion, density, hydration, drug release rate, etc. can be tailored to the drug in question and the physiological characteristics of the target delivery site (15).

Enhancers for Other Modes of Absorption

Many physical and enzymatic barriers can prevent successful delivery of active pharmaceutical ingredients by noninvasive, nonoral routes. It is not surprising, therefore, that there is great interest in excipients that can overcome such obstacles.

Transdermal delivery is a case in point. The skin, particularly the stratum corneum presents a formidable barrier to diffusion. Materials used to enhance its permeability have ranged from simple solvents such as ethanol or propylene glycol to aromatic chemicals such as terpenoids. Such penetration enhancers appear to work by disrupting the lipid domains in the stratum corneum that reduce permeability (16). A bespoke penetration enhancer, laurocapram (Azone), was developed in the late 1970s for use in transdermal delivery but its use in commercial products appears to be limited (17).

Entry via nasal or buccal mucosa allows the delivery of peptides or other labile drugs that are highly potent (low-dose drugs) and that do not have steep dose-response relationships. Absorption enhancement requires increased contact time and reduced clearance rate (in the case of nasal delivery), thereby optimizing conditions for mucosal diffusion. Excipients that enhance nasal absorption include

Fig. 1 Effect of oleic acid on propranolol bioavailability. (From Ref. 8.)

phospholipids to enhance mucosal permeability and agents that imbibe water and become mucoadhesive (e.g., glyceryl mono oleate). In addition, the gelling agents hydroxypropyl cellulose and polyacrylic acid promote absorption of insulin in dogs (18). These findings, however, have not been used to find a commercially viable product for intranasal delivery of insulin, presumably due to insulin's narrow therapeutic index. However, intranasal delivery systems for calcitonin, a macromolecule with a much safer dose-response relationship, have been commercialized.

EXCIPIENTS FOR DRUG TARGETING

The 1990s saw an explosion in knowledge and understanding of the roles that natural mediators play in physiological and pathological processes. At the same time, biotechnology has made it feasible to manufacture such mediators relatively cheaply and in large quantities, thereby affording possibilities for use as therapeutic agents. However, effective delivery remains a formidable challenge from the efficacy, safety, and patient-convenience perspective. Most natural mediators are highly potent, extremely labile, and may need to be delivered to a specific organ or cellular target. Conventional oral dosage is not usually feasible due to the hostile environment and enzymatic barriers along the GI tract. Parenteral administration is hardly desirable for chronic therapy. Therefore, many biotechnology products need to be combined with materials that afford protection against destruction, reduce elimination rate, or target a specific site so that activity is enhanced and toxicity minimized. The level of interest and activity in this area supports the view that more effective delivery systems are required if the promise of biotechnology is to be realized. Hence, it is likely that the search for absorption-enhancing excipients for such materials will continue unabated.

Carriers for biopharmaceutical therapeutic agents range from well-established excipients of natural origin to custom-made synthetic materials with putatively enhanced protective or targeting features. Natural or semisynthetic materials predominate however. Sources as diverse as primitive marine plants (chitosans and alginates), plant or animal phospholipids (egg and seed lecithin), and mammalian collagens (gelatin) are being mined for useful delivery or targeting aids, as well as for components of complex formulations such as microemulsions or liposomes. The wide use of biological materials may mean that Mother Nature produces more suitable biopolymers than the synthetic chemist. More plausibly, it may reflect

the need for long and expensive safety evaluation of novel synthetic materials prior to use in man. This hinders timely evaluation other than in vitro or animal models.

More esoteric materials that confer target specificity include glycoproteins, recombinant proteins, or monoclonal antibodies (19). To date, clinical performance of such carrier systems has been disappointing. Further refinement of concepts and materials may be necessary before the performance matches the promise.

Attenuated adenoviruses have been used as vectors where delivery to cell nuclei is required (e.g., in gene medicine). It is a moot point whether these or other targeting or carrier materials are "excipients" part of a prodrug or something in-between. The boundaries between "active" and "inactive" materials are much less clear in such cases. The traditional approach of evaluating a novel entity in its own right in animal safety programs and then formulating with "inert" materials is inappropriate with sophisticated delivery systems because of the important effect of the adjuvant on disposition and kinetics of the active ingredient.

EXCIPIENTS AS STABILIZERS

Product quality can be compromised during manufacture, transport, storage or use. The causes of deterioration can be manifold and product-specific. They include microbial spoilage or chemical transformation of the active or physical changes that alter performance in vivo. Deterioration can compromise safety or make the medication less attractive, which means it may not be used. Excipients can contribute to or cause such changes unless carefully screened for possible interactions in preformulation studies.

Cases where excipients have the opposite effect and stabilize labile drugs are less common. Nevertheless, they have been shown to reduce degradation rates of drugs that are photolabile, oxidizable, or degradable consequent to inter- or intramolecular reactions (20). Stabilization strategies include the following:

1. Formulation with an excipient whose light absorption spectrum overlaps that of the photolabile drug. This is the so-called spectral overlay approach;
2. Using an antioxidant in formulations that are susceptible to degradation by oxidation. This approach has been particularly successful in vitamin-containing products
3. Using an excipient that "hinders" association of groups in the same molecule, in adjacent molecules, or in the vehicle that can interact and cause degradation. There

are several reports of cyclodextrins effecting such “steric stabilizations.” Polyethylene glycol also has been shown to stabilize an ointment formulation by preventing formation of inactive rearrangement products.

Less esoteric but equally important stabilizers include preservatives in liquid products to prevent microbial growth and buffers to provide an environment conducive to good stability where degradation is pH-related. Chelating agents also are used as stabilizers to prevent heavy metals from catalyzing degradation.

EXCIPIENTS AS PROCESS AIDS

The vast majority of medicinal products are manufactured by high-speed, largely automated processes for reasons that are related as much to safety and quality as to cost of goods. Excipients that aid in processing include the following:

1. The almost universal use of lubricants such as stearates in tablets and capsules to reduce friction between moving parts during compression or compaction;
2. Excipients that aid powder flow in tablet or capsule manufacture. Materials such as colloidal silica improve flow from hopper to die and aid packdown in the die or capsule shell. Accuracy and consistency of fill and associated dose is thereby improved
3. Compression aids to help form a good compact, whether on dry granulation (slugging) prior to tableting or on tablet compression. Most are derived from plant, animal, or mineral origin (microcrystalline cellulose, lactose, or magnesium carbonate)
4. Agents such as human or bovine serum albumin that are used in the manufacture of biotechnology-based products. These avoid adsorption of the protein to flexible tubing, filters, and other process equipment
5. Stabilizers to protect the drug from processing conditions that might otherwise be deleterious. It is common to use “cryoprotectants” such as sugars, polyhydric alcohols or dextrans in lyophilized parenteral biotechnology products to prevent inactivation during freezing. A similar approach has also been used to prevent liposomal aggregation and leakage (21).

“Flow aids” also can help performance in cases where the delivery device is an integral part of the medication. Products for pulmonary delivery are often formulated as dry powders that are inhaled via the oral cavity. The fine-particle nature of the medicinal agent, which may be vital for efficient delivery to the

bronchial target area, militates against good flow. Materials such as lactose or mannitol (of appropriate particle size) can enhance flow or act as a “carrier” from the dose unit (usually a capsule) through the inhalation delivery device to the oral cavity on inspiration. They are widely used for these purposes in inhalation formulations of anti-asthmatic agents such as salbutamol and budesonide (22, 23). The recombinant therapeutic proteins human deoxyribonuclease (used to treat cystic fibrosis) and human granulocyte colony stimulating factor (g-CSF) are also formulated with “carriers” to aid pulmonary delivery (24).

The adherence of very fine particles to larger ones can solve segregation problems when mixing powders containing particles of differing size or shape. If the fine particles can associate with their larger companions due to some surface effect, “ordered mixing” ensues and homogeneity is assured during subsequent processing (25).

Process aids do not usually contribute to the performance of the dosage form in terms of quality or in vivo performance. Indeed, lubricants, because of their hydrophobic nature, can hinder disintegration and dissolution of solid dosage forms unless the level and mode of incorporation is carefully characterized and controlled. Thus, in addition to drug-excipient interactions, the potential for interexcipient competition and incompatibility must be considered and studied.

DRUG–EXCIPIENT INTERACTIONS

Despite the earlier account of excipients acting as stabilizers, it is fair to state that there are far more cases on record of excipients adversely affecting quality. Degradation may be caused by interaction between functional groups in the excipient and those associated with the drug. Many small-molecule drugs contain primary, secondary, or tertiary amino groups and these have the propensity to interact with aldehydic groups in sugars or volatile aldehydes present as residues. Chemical interaction can result in degradation of the drug substance to inactive moieties with loss of efficacy where degradation is excessive. Even when degradation is modest, it is possible that the formed degradation products may compromise safety.

Physical interactions between drug and excipient also can compromise quality. Adsorption of drug by microcrystalline cellulose resulted in drug dissolution being less than complete (26). Interaction between chloramphenicol stearate and colloidal silica during grinding led to polymorphic transformation (27).

Fig. 2 Water vapor sorption isotherm for microcrystalline cellulose at 25°C. (From Ref. 30.)

Excipients may contribute to degradation even when not directly interacting with active moieties. Soluble materials may alter pH or ionic strength, thereby accelerating hydrolytic reactions in liquid presentations. Such effects may be accentuated during processing. For instance, sterilization by autoclaving, while of short duration, may cause significant degradation product formation because of the high temperature involved. Dextrose is widely used in parenteral nutrition solutions or as a tonicity modifier in other parenterals. Sterilization by autoclaving can cause isomerization to fructose and formation of 5-Hydroxymethyl furfuraldehyde in electrolyte-containing solutions (28). At the other extremes of processing, succinate buffer was shown to crystallize during the freezing stage of lyophilization, with associated reduction of pH and unfolding of gamma interferon (29). It is important to identify and characterize such “process stresses” during dosage-form development and tailor processing conditions accordingly.

Microcrystalline cellulose is a partially depolymerized cellulose that is part-crystalline/part noncrystalline and hygroscopic. Adsorbed water is not held in any “bound” state but will rapidly equilibrate with the environment during processing or storage (30) (Fig. 2). Thus, it is possible that in a dosage form, water can be sequestered by a more hygroscopic active ingredient. If the drug is moisture sensitive, degradation may follow. Stabilization may be possible by drying prior to use, but loss of water may make it a less effective compression aid (31).

Fig. 3 Potential residues in microcrystalline cellulose.

Microcrystalline cellulose may also contain low levels of nonsaccharide organic residues. These emanate from lignin, a cross-linked biopolymer made up primarily of the three allylic alcohols/phenols in the wood chip starting material (Fig. 3) (32).

It is also possible that degradation products of these phenols, or free radical combinations, may be present, with potential for chemical interaction with the drug.

This focus on residues associated with microcrystalline cellulose is not to denigrate it as an excipient. It is and will remain a most valuable formulation aid that can help compression, disintegration, and flow, as well as acting as a general diluent in solid-dose formulation (33). It can also be a useful additive in liquid products. Indeed, the knowledge available on microcrystalline cellulose interactions probably reflects the level of interest in such a useful material. Rather, the intent is to illustrate how excipients, or residues contained in them, can interact with active ingredients in a number of ways. The first commandment for the formulator is arguably to “know your drug,” but it is also important to be aware of the composition, residues, and other behaviors of excipients.

STABILITY OF EXCIPIENTS

Excipients can lose quality over time. Oils, paraffins, and flavors oxidize; cellulose gums may lose viscosity. Polymeric materials used in film coating or to modify release from the dosage form can age due to changes in glass transition temperature. This can lead to changes in elasticity, permeability, and hydration rate and associated changes in release properties or appearance (34).

Preservatives such as benzoic acid or the para hydroxybenzoates are volatile and can be lost during product manufacture if the process involves heating. Loss during product storage is also feasible if containers are permeable to passage of organic vapors. Acetate buffer is volatile at low pH and can be lost during the drying stages of lyophilization. Such behaviors reinforce the need to know the behaviors of excipients as well as of the active ingredient so that appropriate processing, storage conditions, and “use by” periods are stipulated where necessary.

IMPURITIES IN EXCIPIENTS

Excipients, like drug substances contain process residues, degradation products or other structural deviants formed during manufacture. Historically, it was not unusual for

Fig. 4 Potential residues in lactose.

adulterants to be added to “bulk up” the commodity. Thankfully, a combination of better analytical techniques, vendor certification programs, and quality audit systems should mean that adulteration is largely a thing of the past. However, constant vigilance is necessary. As recently as 1996, renal failure in children in Haiti was ascribed to use of glycerol contaminated with diethylene glycol in a liquid paracetamol product (35).

Residues in excipients can affect quality and performance by interacting with the drug or other key components. Reducing sugar impurities in mannitol were responsible for the oxidative degradation of a cyclic heptapeptide (36).

Lactose is one of the most widely used excipients in tablet manufacture. It is available in a number of different forms, differing in hydration and crystal states. Isolation and purification may involve treatment with sulphur dioxide (37). However, there are no reports of complications from residues of this powerful oxidizing agent.

Lactose is a disaccharide comprised of glucose and galactose units. These reducing sugars are reported to be present in spray dried lactose (38), as is the hexose degradant 5-hydroxymethyl furfural (39). This aldehyde has the potential for additional reactions with primary amino groups, Schiff Base formation and color development (Fig. 4) (40).

Drugs containing secondary amine groups also can be degraded. Maillard reaction products have been reported in capsules containing lactose and the antidepressant fluoxetine (41). This reaction is also reported extensively in publications concerned with the food industry. High temperatures and low moisture contents associated with food processing induces caramelization of sugars and oxidation of fatty acids to aldehydes, lactones, ketones, alcohols, and esters (42, 43). It would not be surprising if such degradation products were generated in the same materials used in pharmaceutical dosage forms. Unfortunately, most pharmacopoeial monographs do not list such organic contaminants. Also, some excipient vendors are reluctant to share information on residues and contaminants with customers. The pharmaceutical industry generally represents only a small proportion of business for such commodity providers. Hence, it is difficult to be persuasive on the need for individualized standards and controls. Therefore, the following list (Table 2) cannot be

Table 2 Potential residues in common excipients

Excipient	Residue
PVP, Polysorbates, benzyl alcohol	Peroxides
Magnesium stearate, fixed oils, paraffins	Antioxidants
Lactose	Aldehydes, reducing sugars
Benzyl alcohol	Benzaldehyde
Polyethylene glycol	Aldehydes, peroxides, organic acids
Microcrystalline cellulose	Lignin, hemicelluloses

considered as comprehensive because of this unsatisfactory state of affairs.

Excipient residues may also compromise safety or tolerance. Wool fat or lanolin derived from sheep wool may contain low levels of insecticides from sheep treated for parasites. These insecticide levels are probably too low to cause direct toxicity, but may cause allergic reactions when lanolin in cosmetics or topical medicaments is applied to the skin.

Paradoxically, excipient residues such as antioxidants may inadvertently act as stabilizers of the drug substance. Unheralded removal by the vendor or replacement by a different type of stabilizer could precipitate an unheralded product stability crisis leading to recall from the market. Such a possibility highlights the need for agreed change control systems between the pharmaceutical manufacturer and the excipient vendor.

SAFETY OF EXCIPIENTS

Although excipients have traditionally been considered “inert,” it is now well accepted that some carry the potential for untoward effects. These can range from the inconvenient to the serious, be general or patient-specific, and may or may not be dose-related. The effect may be ascribable to the excipient itself or to a residue from the starting material or the process of manufacture.

Lactose is one of the most widely used tablet excipients. However, 5–10% of the population of the United Kingdom suffers from lactose malabsorption (44), nor is there reason to suppose that this percentage is lower in other countries. Lack of the lactase enzyme leads to fermentation by colonic bacteria, with formation of lactic acid and carbon dioxide causing stomach cramps, diarrhea, and vomiting (45). Whether such clinical symptoms are manifest following ingestion of the levels

normally present in dosage forms is not known, but such phenomena may sometimes explain minor side effects regularly reported during the monitoring that accompanies volunteer Phase I studies.

Malabsorption of the cereal protein gluten is another potential source of untoward effects from excipients. This condition demands a gluten-free diet. Most starches utilized in medicinal products are now gluten-free but gluten-containing materials have been used as film formers in microencapsulated products (46). There is also a possibility that gluten could be present in excipients that utilize cereal derivatives as starting materials or bases (e.g., dry powder flavors that sometimes use maltodextrin bases).

Sucrose is a very effective sweetener, particularly for liquids dosed to children. Its propensity to cause dental caries and the complications it poses in the management of diabetes may have contributed to its progressive removal from medicinal products despite its continuing widespread use in foods and confectionery. Sorbitol is another excellent sweetening agent and has been used as a replacement for sucrose in oral liquid products. It has the propensity to cause diarrhea and flatulence, although the effect may only be manifest at high doses. However, there may be additive effects (e.g., if it is formulated with active ingredients that are also associated with GI intolerance, such as antibiotics).

Synthetic sweeteners have had checkered careers as excipients (47). Cyclamate was banned in the United States following reports of carcinogenicity and withdrawal of generally regarded as safe (GRAS) status in 1969. It remains banned despite additional studies to clarify safety and attempts at reinstatement. It remains acceptable in Europe.

Saccharin is equally controversial. It also is suspected as being a carcinogen due to cyclohexylamine formation, possibly by gut flora, on ingestion (48). It was banned as a food additive by the Food and Drug Administration (FDA) in 1977, but has remained available consequent to regular congressional moratoria on the proposed ban. It is not permitted in Canada except for diabetic beverages and foods.

The flavoring agent sodium glutamate is sometimes used to flavor protein supplements or liver extracts. Flushing, headache, and chest pain have been ascribed to its presence, albeit after food intake rather than medication. This is the background to the so-called Chinese restaurant syndrome (49).

Aspartame is a newer sweetener/flavor enhancer but it too may cause angiodema and urticaria. It is contraindicated in patients suffering from phenylketone urea, as hydrolysis can lead to formation of phenylalanine.

Aspartame also can hydrolyze in solution to form a diketopiperazine derivative and can participate in Michael-type addition reactions with olefines susceptible to nucleophilic attack. The products of such interactions, if they occur, will be drug and formulation-specific, and it is likely that their safety characteristics will be unknown (45).

The use of benzyl alcohol as a local anesthetic was previously discussed. It is also used as a preservative in parenteral dosage forms. However, there is some evidence that benzyl alcohol is neurotoxic and its use is contraindicated in the United Kingdom in children under 3 years of age (50).

The literature is replete with reports of various allergic-type reactions to preservatives (parabens, chlorocresol), antioxidants (propyl gallate, metabisulphite), surfactants and solvents. The list is too long to be discussed in this article but Ref. 48 contains a very useful compilation and discussion of immunotoxic events seen with various dosage form additives.

Many of these studies involved application of copious amounts to animal skin or to human volunteers in Phase I studies. Others concerned reports of reactions in people suffering from pre-existing allergic conditions. Reports of side effects must, therefore, be viewed from such perspectives and the possibilities for side effects weighed against the widespread use of the same materials in food, confectionery, cosmetic, and household products as well as in medicines. This is not to belittle the hypersensitivity and other reported reactions but unless these are put into context, there may be further constraints on excipient usage and unrealistic demands for "totally inert" formulation adjuvants.

Adverse reactions may be caused by the excipient *per se* but by a residue. HIV infection in humans and spongiform encephalopathies in cattle have raised the specter of viral transmission by materials as diverse as human and bovine serum albumin, lactose, gelatin, fatty acids, or their salts, as well as polyols such as glycerol. It is generally accepted that screening procedures for blood donors and the heat treatment usually employed for sterilizing human serum albumin (minimum 10 h at 60°C), originally introduced to guard against hepatitis infection, provides good lethality against the HIV virus. However, the prions associated with spongiform encephalopathies are so resistant to heat and other forms of sterilization that removal is more problematic. Consequently, the use of vegetable sources for fatty acid and organic alcohol-type excipients is becoming more common. Whether gelatin capsules will be replaced by starch or cellulose gum-based alternatives (for the same reason) remains to be seen.

Fig. 5 Mechanism of solubilization by cyclodextrins. (Reproduced from CyDex Inc.)

NOVEL EXCIPIENTS

It might be expected that the increased knowledge of pathological processes and drug-receptor dynamics, along with the relentless pressure for manufacturing efficiencies and economies of scale that have been the hallmark of the 1990s, would also demand and generate new and better formulation aids. This has not happened. Indeed, some have implied that excipients available in 2000 A.D. are not very different from those that were available in 2000 B.C. (51). While clearly calculated to amuse, the assertion contains a grain of truth. Only a handful of novel excipients have emerged over the past 20 years.

The reasons for this are not difficult to understand. Like novel pharmacological agents, a novel excipient must go through numerous safety and metabolic evaluation processes before it can be used in humans. In essence, it would be necessary to apply for a Type 4 Drug Master File in the United States, or a Certificate of Suitability in European Union (EU) countries (50). Such safety and filing programs are expensive and time-consuming. Furthermore, it is difficult to prove “lack of activity” in any material. Excipients are not subject to prescription or pharmacovigilance monitoring, therefore, they need to be “squeaky clean” before “blanket approval” is forthcoming. While a novel excipient can be evaluated at the same time as a novel drug, few organizations wish to put their investment in a novel drug at risk by partnering it with an unproven excipient. Therefore, novel excipients are likely to remain scarce commodities. However, a number of materials considered as “novel” are evincing interest as formulation aids.

Cyclic Glucose Polymers

Cyclodextrins are not new molecular entities. They were first reported a century ago. However, it is only relatively

recently that their potential as formulation aids has been recognized. Their capability to stabilize labile drugs has already been mentioned. They can also be used to solubilize highly insoluble molecules as, with the insertion of the drug in the annulus, the complex largely acquires the solubility characteristics of the cyclodextrin (52) (Fig. 5). Inclusion complexes have also been used to successfully mask taste or odor, reduce sublimation of drugs with high volatility (53), and enhance thermal stability (54).

The so-called parent cyclodextrins viz the alpha, beta, and other forms (Fig. 6) have properties that may have prevented widespread use as formulation adjuvants. The moderate solubility and the perceived need to form molar complexes meant that their use would be limited to low-dose, highly potent compounds. Furthermore, β -Cyclodextrin in particular could not be used parenterally because of renal nephrotoxicity. This was ascribed to its low solubility possibly associated with the propensity to form a molecular complex with cholesterol *in vivo* and precipitate in the proximal renal tubule. Thus, the potentially most useful application viz dissolution of poorly soluble compounds for injection could not be countenanced. However, β -Cyclodextrin is currently a well-established excipient in oral dosage forms and has recently been allocated monographs (as Betadex) in the European Pharmacopoeia (EP) 2000 and in the U.S. National Formulary, NF 19.

It is also encouraging that derivatized cyclodextrins with greater solubility are now available. The hydroxypropyl and sulphobutyl ether derivatives of β -Cyclodextrin (Fig. 7) have much greater solubilities than the parent material. Indeed, sulphobutyl ether was deliberately developed for use with parenterals in the knowledge that many novel drug substances are poorly soluble. Both these forms have been subjected to comprehensive safety evaluation programs (parenteral in the case of the sulphobutyl ether), and Drug Master Files have been lodged with the FDA. Such

Parent Cyclodextrin	a	b	g

Cavity Volume (Å) ³	~174	~262	~472

Fig. 6 Properties and functional groups of some cyclodextrins. (Reproduced from CyDex Inc.)

initiative and commitment on the part of the manufacturers of these newer agents is particularly praiseworthy in light of the costly safety evaluation programs. It may well be that with the availability of such “more suitable” cyclodextrins, they will find a valuable niche in the armamentarium of the formulation scientist. The references cited below comprise two excellent reviews of the promise, properties, and limitations of cyclodextrins (55, 56).

Thus, cyclodextrins are a family of excipients, each with somewhat different properties that allow the

possibility of matching individual cyclodextrins to specific drugs to compensate for a deficiency or to aid performance in some way.

Fluorocarbons

The replacement of chlorofluorocarbon (CFC) propellants with the nonozone-depleting hydrofluorocarbons (HFCs) merit mention for two reasons. First, it illustrates how environmental impact can be an important selection

Fig. 7 Functional groups of novel cyclodextrins. (Reproduced from CyDex Inc.)

criterion at a time when “green” issues are high profile. Second, HFCs were developed and evaluated for safety and delivery capability by a consortium of pharmaceutical companies, with costs shared and evaluation programs defined by prior agreement between end-users and propellant manufacturers. Such collaboration could be employed usefully in the future to develop novel excipients for delivery or targeting. The benefits would undoubtedly accrue to all.

Polymeric Targeting or Delivery Aids

Many publications, particularly from academic institutes, contain information concerning synthetic or semisynthetic polymers, which are designed to enhance targeting or delivery properties. However, evaluation of the effect of such material on performance has been invariably confined to in vitro work or perhaps studies in rodents. Clearance for use in humans has not been obtained. Therefore, these substances cannot be considered as excipients that are readily available to the formulation technologist.

If few novel delivery materials become available in the future, the formulation scientist may have to rely on using mixtures of established excipients that, in combination, have properties that are “greater than the sum of the parts” in terms of viscoelasticity, diffusivity, tissue/organ specificity or other desirable targeting or delivery features. Such approaches seem likely to provide considerable scope for creative approaches, and for the formulation technologist, it should be an exciting and fulfilling road to travel.

EXCIPIENT SELECTION

The nature and properties of the active ingredient dictate the choice of an excipient, the dosage form to be elaborated, and the process by which it is manufactured. It is also important to know the patient group and clinical condition. The mode of use of the medication and the envisaged dose must also be considered. Candidate excipients should then be evaluated to demonstrate that they function in the manner intended (do what they are meant to do) and do not adversely interact with the drug, or with other excipients. Obviously, they should not have any pharmacological effect and should not otherwise compromise safety or tolerance.

It is also necessary to consider the regulatory status of excipients and any country-specific requirements or constraints. The U.S. and Japanese regulatory agencies

publish lists of excipients used in medicinal products (57, 58). The materials listed in these compendia can generally be considered suitable for administration by the route for which they are already being used. For materials with no history of previous use, evidence must be provided that they do not compromise patient safety nor induce any other undesirable effects.

SOURCING EXCIPIENTS

Excipients can be crucial determinants of product performance and quality. Thus, they should be sourced directly from a reputable vendor who has quality systems in place to ensure consistent manufacture and control. Procurement from brokers is to be discouraged. Auditing such providers for the presence of quality systems and controls should be the norm, particularly if they are new suppliers to the pharmaceutical industry. A validation program should be put in place to establish reliability of the supply source (59). This program should take the following into account:

1. The nature of the excipient and medicinal product in which it will be used
2. The conditions under which the materials are manufactured and controlled
3. The nature and status of the supplier, and his understanding of the Good Manufacturing Practice (GMP) requirements of the pharmaceutical industry
4. The Quality Assurance system of the manufacturer. Excipients, unlike active ingredients, are not currently subject to regulatory control in terms of GMP unless they are novel materials (in which case preapproval inspection for GMP compliance is necessary). However, the Guide to Good Manufacturing Practice for Bulk Pharmaceutical Excipients, elaborated by the International Pharmaceutical Excipients Councils (IPEC) of Europe and the U.S. while not having any regulatory status, provides much useful information on quality systems and is a good reference for performing audits of excipient facilities (60, 61).

A particular drug or dosage form may have features that rely on the presence of excipients for stabilization, delivery, or other performance parameters. Alternatively, the excipient may need to have additional features to render it suitable for the product in question (e.g., density, absence of a particular residue, etc.). In such cases it may be necessary to agree to extra quality tests and limits over and above those demanded by pharmacopoeias or applied by the vendor.

It is also prudent to be aware of the materials, reagents, and solvent used in the manufacture of the excipient and consider potential interactions between such residues and the active ingredient. It may also be advisable to agree to a Change Control notification procedure with the vendor, to avoid the introduction of new materials in the manufacture of the excipient without prior consideration of the possible impact on the medicinal product.

CONCLUSION

Traditional attitudes that viewed excipients as "inert" materials are long outmoded. It is now well accepted that they are not merely place fillers but can be true "partners" of the active ingredient in many medicinal products and have the potential to enhance or possibly adversely affect performance. As such, their choice, quality control, mode of inclusion, stability, and performance characteristics merit the same attention as the active ingredient. Thus, knowledge of excipients, their foibles, and requirements for handling, processing, and storage are powerful assets in the armamentarium of the pharmaceutical technologist.

EVAPORATION AND EVAPORATORS

David P. Kessler

Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

In the general sense, *evaporation* refers to any change in phase of a component from liquid to gas. *Vaporization*, sometimes used interchangeably with *evaporation*, is at times specifically used to designate the total change of a liquid phase to gas (vapor).

In this article only the term *evaporation* will be used. Evaporation will be defined as processes carried out in process equipment conventionally classified as *evaporators*. This, in turn, implies that nonequipment-contained classes of evaporation, such as solar ponds and oil tanker spills, will be ignored.

Evaporators are used to increase the concentration of relatively nonvolatile dissolved or suspended components in a solution or slurry (the *liquor*) by evaporating portions of the liquid phase using energy supplied by a *medium*, often steam. The dissolved or suspended components do not appear in the vapor phase to a substantial extent. (If they do, the process is referred to as *distillation*.)

Other methods that will not be discussed here, but also can be used to increase concentration (some with and some without concomitant evaporation) are reverse osmosis, ion exchange, dialysis, electrodialysis, osmotic distillation, and applications that involve fluidized beds, cooling towers, or evaporation of aerosols.

In most evaporators, the solvent or suspending phase is primarily or totally one constituent, most frequently water. The important product in evaporation can be either the more concentrated mixture left behind or the overhead vapor (which is often, but not necessarily, subsequently condensed).

The overhead solvent vapor in solvent recovery processes or boiler water vapor in power plant applications typifies vapor products. *Blowdown* refers to the periodic or continuous purging of the bottoms used to control buildup of undesirable material in the liquid phase when producing a vapor product (1).

Some processes of evaporation can be accompanied by crystallization, as the residual liquor grows more and more concentrated. Carried yet further, evaporation evolves to *drying* (or dehydration, if the constituent removed is

water), as the bottoms product obtained becomes primarily solid rather than liquid.

TYPICAL APPLICATIONS FOR EVAPORATORS

Historically, a classic example of an evaporation process is the production of table salt. Maple syrup has traditionally been produced by evaporation of sap. Concentration of black liquor from pulp and paper processing constitutes a large-volume present application. Evaporators are also employed in such disparate uses as: desalination of seawater, nuclear fuel reprocessing (1), radioactive waste treatment (2, 3), preparation of boiler feed waters, and production of sodium hydroxide (2). They are used to concentrate stillage waste in fermentation processes, waste brines, inorganic salts in fertilizer production, and rinse liquids used in metal finishing, as well as in the production of sugar, vitamin C, caustic soda, dyes, and juice concentrates, and for solvent recovery in pharmaceutical processes.

TYPES OF EVAPORATORS

Extended discussion of types (including photographs and schematic diagrams), design, and operation of evaporators can be found in the literature (4–6).

Because evaporation of a liquid phase usually requires addition of large amounts of thermal energy, the method of transferring this heat to the liquor tends to dominate evaporator capital cost. The source of heat for evaporators is usually a medium such as hot combustion gases or a condensing vapor, typically steam. Molten salts and electrical resistance heaters are less commonly used sources of thermal energy.

Flash evaporators operate by an adiabatic decrease of the pressure on a liquid that has been previously heated. These were first used for production of potable water on ships; now they are used for more general brackish waters and seawater as well as for processed liquids (7).

Disk or *cascade* evaporators use the partial immersion of either disks mounted perpendicular to, or bars mounted parallel to a rotating shaft to carry films of liquid into a hot gas stream (8).

The most efficient method of transferring the energy of a heating medium to the liquor is direct injection of the heating medium. Because of the consequent contamination of the liquor with the heating medium, this method of heat transfer is of relatively less importance in the pharmaceutical industry and will not be discussed here.

The more useful methods for pharmaceutical products maintain purity at the expense of additional resistance to heat transfer by interposing a solid wall of some thermally conductive material between the heating medium and the liquor. The solid wall is usually metallic, but can be coated with materials such as glass, porcelain enamel, or polymers. Glass or ceramic themselves can be used for walls.

The solid wall can be the wall of the evaporator itself, as in *jacketed* evaporators. The area available for heat transfer in jacketed vessels, however, is quite limited. Jacketed vessels frequently incorporate some sort of internal agitator.

Heat transfer can be supplied from within a vessel by a heating coil, but again, the available heat transfer area is not large; however, such coils can be designed in ways that

make their removal for cleaning relatively easy. The alternative is to have the heat exchange external to the main chamber of the evaporator.

Some applications use plate-type exchangers. In plate exchangers, the bounding surface may be in the plate-and-frame form (parallel plates with the heating medium and the liquor flowing in alternate interstitial spaces), or in a spiral-plate configuration that contains a concentric pair of spiral passages (7). Such exchangers can be cleaned easily. They do, however, require a large gasketed area. Fig. 1 shows a typical plate-type evaporator.

The most common geometry for the separating surface between the heating medium and the liquor is probably that of tube bundles, which can be oriented either horizontally or vertically, with the liquor flowing on either the outside or the inside of the tubes. Depending on the application, the tube bundle can be either inside or outside the vessel in which the evaporation takes place.

The heating element of an evaporator is sometimes referred to as a *calandria*. Usually this term is applied to a heating system in which the liquor rises through a vertical tube bundle surrounded by the heating medium and then descends through a central well.

The *short-tube vertical* evaporator is an early type that still sees considerable industrial use. The heating element,

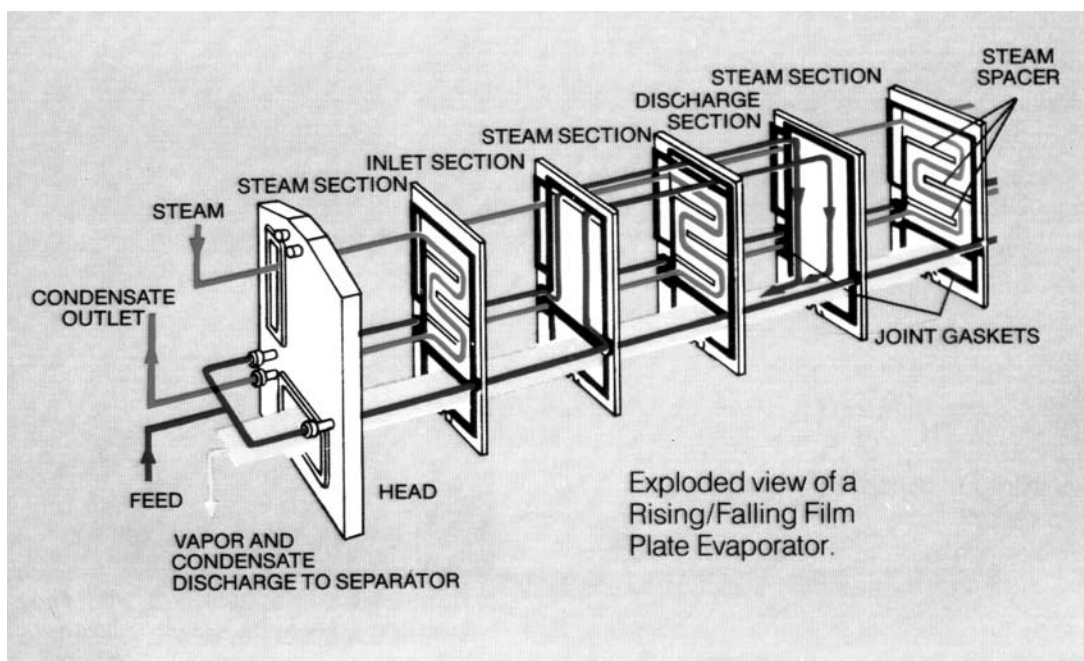

Fig. 1 Exploded view of rising/falling film plate evaporator. (Courtesy of APV Crepaco, Inc., APV Americas, Rosemont, IL—An Invensys Company.)

a vertical bundle of tubes around a center well, is sometimes colloquially referred to as the basket. Circulation is upward through the tubes, the *rising film* mode, and then downward through the central well or *downtake*. Liquid boils in the tubes, which decreases the overall density therein and thus creates the driving force for circulation, since the density of the (nonboiling) fluid in the downtake is greater than that in the tubes.

Mechanical cleaning is fairly easy with such units, and the capital investment is relatively low. Circulation stops, however, if the heat input is interrupted, creating the danger of the settling of any solids suspended in the liquor. This type of unit is not well suited to viscous liquids because of the low heat transfer coefficients associated with the low velocities of natural convection (8). Short-tube vertical evaporators have largely been surpassed by other types, particularly for applications involving liquors that foam, deposit excessive scale, are excessively viscous, or are heat sensitive.

Long-tube vertical evaporators are normally the cheapest per unit of capacity (8). When operated in the rising film mode, temperature variation along the inside of the tubes is both substantial and difficult to predict. The variation in pressure from high at the bottom to low at the top normally means that the liquid enters the bottom of the tubes below its boiling temperature. The liquid is subsequently heated to boiling as it rises, and the boiling temperature simultaneously decreases as the pressure decreases toward the top of the tube (assuming any boiling point rise from increasing concentration is overshadowed by the effect of the reduced pressure on the boiling point).

By operating a long-tube evaporator in the *falling film* mode, the problem of temperature variation induced by pressure differences is mitigated. Here, a film of liquid surrounding a gas core flows down the walls of the tube, so pressure drop is very much less than in the rising film mode. The low residence time of the falling film units makes them useful for heat-sensitive materials, but the necessity of maintaining a film on the walls of the tubes makes feed distribution a problem. They are readily adapted to sanitary processing. Evaporators that combine rising film sections and falling film sections in the same unit are also available.

Forced circulation evaporators have relatively higher heat transfer coefficients, and are somewhat less subject to fouling, salting, and scaling. This advantage is offset by both the cost of external power required for the circulating machinery and a relatively high holdup (8). At times they more frequently experience plugging from deposits detached from the walls of the unit by the force of the circulating fluid. The introduction of a pump may lead to mechanical problems, particularly with liquors that are slurries.

Liquor velocities required to prevent surface deposits are often greater than can be obtained with natural circulation at reasonably low temperature differences (9). In addition to mitigating scale formation, forced circulation also improves the heat transfer coefficient.

For viscous liquids, one way to increase the heat transferred is to improve the heat transfer coefficient by scraping or stirring the fluid adjacent to the wall, as in *agitated film* or *wiped film* evaporators. Accommodation of the mechanical devices used to mix the fluid close to the wall requires a fairly large diameter tube, so these devices tend to consist of only a single tube; thus, heat transfer area is relatively small. The introduction of moving mechanical parts may lead to maintenance problems.

In *horizontal tube* evaporators, the liquor is usually on the outside of the tubes and the heating medium on the inside. Rather than submerging the tubes, the boiling liquid is sometimes sprayed on the outside of the tubes. This gives a performance approaching that of falling film evaporators (8).

Evaporators can be operated at a variety of pressures (9). Reduced pressure, with its concomitant reduction in boiling temperature, offers advantages for heat-sensitive materials and materials that are sensitive to exposure to air.

Evaporation operations are often staged in *multiple effect* systems (1) to achieve better efficiency. Such systems can have a variety of relative directions for flow of liquor and vapor. A typical example of such staging is illustrated in Figs. 2 and 3.

Detailed discussion of the advantages and disadvantages of various types of evaporators is available (8). A table summarizing the advantages and disadvantages of common types of evaporators also is available (10).

Since most evaporators are purchased from outside suppliers either prefabricated or on-site-fabricated, such suppliers can be an excellent source of information on selection of evaporator type. Suppliers and addresses can be found in the literature (11, 12).

DESIGN OF EVAPORATORS

A number of publications have addressed the design of evaporators at both the elementary and complex levels (1, 2, 7–9, 13–18). The reader is referred to these and to their bibliographies for details.

Efficiency of steam-heated evaporators is commonly described in terms of steam economy, defined as the pounds of solvent evaporated per pound of steam consumed (7).

Fig. 2 Two-effect rising/falling film plate evaporator. (Courtesy of APV Crepaco, Inc., APV Americas, Rosemont, IL—An Invensys Company.)

Important to the design of evaporators is the concept of boiling point rise. Boiling point rise, which normally accompanies increasing concentration in a liquor, is defined as the difference between the boiling temperature of the liquor and that of pure water at the same pressure.

A plot of the boiling point of pure water on the abscissa versus the boiling point of the liquor on the ordinate, with lines of constant concentration plotted as a parameter, is known as a Dühring plot. A Dühring plot is unique to the particular chemical species. A monograph summarizing the boiling point rise for a number of inorganic salts, is available (19), as well as information on general equations to predict boiling point rise either empirically or from other thermodynamic properties (9).

During batch operation, the composition of the liquor in the evaporator is continuously changing. For batch

operation in the absence of significant potential and kinetic energy changes, an energy balance on the system constituted by the liquor in the evaporator shows that the sum of the rate of enthalpy removed in the overhead stream and the change in internal energy of the liquor in the evaporator must equal the rate of energy addition as heat:

$$\hat{H}_{ov}\dot{W} + \frac{d(\hat{U}M)}{dt} = \dot{Q} \quad (1)$$

where

\hat{H}_{ov}	enthalpy of overhead vapor (energy/mass)
\dot{W}	mass flow rate of overhead vapor (mass/time)
\hat{U}	internal energy of liquor (energy/mass)
M	mass of liquor (mass)
\dot{Q}	rate of heat input (energy/time)
t	time (time)
()	units

Fig. 3 Two-effect rising/falling film plate evaporator flowsheet. (Courtesy of APV Crepaco, Inc., APV Americas, Rosemont, IL—An Invensys Company.)

A way to estimate vapor enthalpy and data on the internal energy of the liquor as a function of concentration is required.

Even though both the enthalpy and rate of the overhead vapor are often quite constant in time (except for the small sensible thermal energy contribution from the boiling point rise), the rate of heat addition may vary with time because of changes in the overall heat transfer coefficient from surface changes (see below) and because of significant changes in the temperature difference between the liquor and heating medium induced by the boiling point rise. A simple example calculation of batch evaporation can be found in reference (14). The equations involved are similar to those that govern batch distillation.

Many evaporators are operated at substantially steady-state conditions (although heat transfer coefficients will vary slowly with time because of surface changes from scaling, deposition, etc., as noted above). The design of an

evaporator for steady-state operation typically is initiated from the specification of the mass flow rate of material to be processed and its required change in concentration. This information is used in mass balances, which proceed via an energy balance to yield the required rate of heat transfer.

For an evaporator system which has a liquid feed, overhead vapor, and bottoms liquid product, and is used to concentrate species A:

Total mass balance

$$\dot{W}^{(\text{feed})} = \dot{W}^{(\text{overhead vapor})} + \dot{W}^{(\text{bottoms liquid})} \quad (2)$$

Species mass balance

$$\begin{aligned} \dot{W}^{(\text{feed})} x_A^{(\text{feed})} &= \dot{W}^{(\text{overhead vapor})} x_A^{(\text{overhead vapor})} \\ &+ \dot{W}^{(\text{bottoms liquid})} x_A^{(\text{bottoms liquid})} \end{aligned} \quad (3)$$

where

- \dot{W} mass flow rate (total mass/time)
 x mass concentration of species A (mass A/total-mass)

Normally, the feed flow rate and concentration are specified, as are the overhead and bottoms concentrations (the overhead concentration is most often zero). This set of two equations in 2 unknowns can then be solved for the unknown overhead and bottoms mass flow rates.

The required rate of heat transfer can then be calculated from the steady-state energy balance, assuming negligible changes in potential and kinetic energy and no work input (the latter not valid, of course, for vapor recompression evaporators).

$$\dot{Q} = \dot{W}^{(\text{overhead vapor})} \hat{H}^{(\text{overhead vapor})} + \dot{W}^{(\text{bottoms liquid})} \hat{H}^{(\text{bottoms liquid})} - \dot{W}^{(\text{feed})} \hat{H}^{(\text{feed})} \quad (4)$$

where

- \dot{Q} heat transfer rate into system (energy/time)
 \dot{W} flow rate (mass/time)
 \hat{H} enthalpy (energy/mass)

In the above equation, the mass flow rates are known from the mass balance calculation. The enthalpies must be determined from thermodynamic data, which will require specification of the temperature and/or pressure of the stream in combination with the concentrations that were originally specified.

Calculation of the rate of heat transfer required does not of itself determine the heat transfer area required or the configuration thereof. The configuration (tubes, plates, etc.) is typically chosen first, by rules of thumb and experience, depending on the liquor to be processed.

The area is usually calculated, once the configuration is chosen, by using an overall heat transfer coefficient that lumps together all forms of heat transfer in terms of an overall coefficient paired with a characteristic area:

$$\dot{Q} = UAT \quad (5)$$

where

- U overall heat transfer coefficient, valid only when paired with a specified area (energy/time \times length² \times temperature)
 A a specified area normal to heat flow; (e.g., the outside area of the tubes or the inside area of the tubes (length²),
 ΔT Temperature difference between temperature of heating medium and temperature of the liquor

(usually either freestream or bulk temperatures) (temperature).

The overall heat transfer coefficient depends on the properties and flow pattern of the heating medium, the properties and flow pattern of the liquor, the properties of the solid surface that separates the medium and the liquor, and the properties of any deposits at the interface on either side of the separating surface.

In general, heat can be transferred by the three mechanisms of conduction, convection, and radiation (20). In evaporators, the mechanisms of importance are usually convection in the liquor and medium, and conduction through the solid separating them.

In order to calculate the overall heat transfer coefficient in the equation above, the heat transfer properties of the heating medium and the liquor are described in terms of individual heat transfer coefficients, and the heat transfer properties of the separating solid in terms of its thermal conductivity. Deposits at the interface, which one might expect to be described by a thermal conductivity, are usually described instead in terms of either a fouling (heat transfer) coefficient or a "fouling factor" (which is usually defined to have a value of 1000/[fouling coefficient]).

Individual heat transfer coefficients for convection are defined by the equation:

$$\dot{Q} = hAT \quad (6)$$

where

- h individual heat transfer coefficient (energy/time \times length² \times temperature),
 A a characteristic area normal to the flow of heat: typically, the area of the unfouled surface initially in contact with the fluid. In cases where area varies along the heat transfer path, (e.g., tubes), it is necessary to specify on which area the coefficient is based, such as, inside, outside (length²),
 ΔT a specified temperature difference, usually the difference between either the freestream or the bulk temperature and the temperature at the surface.

The rate of heat transfer by conduction can be written in terms of the thermal conductivity:

$$\dot{Q} = kA_{\text{avg}}Tx \quad (7)$$

where

- k thermal conductivity of solid (energy/time \times length \times temperature),
 A_{avg} average area through which heat transfer occurs, e.g., logarithmic mean area for concentric cylinders (length²),

- ΔT temperature drop from one outside surface of the solid to the other outside surface (temperature)
 Δx thickness of solid normal to heat flow (length)

One can relate the overall heat transfer coefficient to the individual steps:

$$\frac{1}{U_{ov}A_{ov}} = \frac{1}{h_{medium}A_{medium}} + \frac{1}{h_{fouling,medium}A_{fouling,medium}} + \frac{x}{kA_{avg,solid}} + \frac{1}{h_{fouling,liquor}A_{fouling,liquor}} + \frac{1}{h_{liquor}A_{liquor}} \quad (8)$$

The overall heat transfer coefficient can be calculated by evaluation of the individual terms in the above equation. Knowledge of the overall temperature drop then permits calculation of the required area. A detailed development of the above is available (5).

The individual heat transfer coefficients for the medium and the liquor can be calculated from general correlations using the properties of the fluid and the velocity fields in the system (20–25). Additional information can be found in the continuing series of the American Society of Mechanical Engineers (26). Detailed studies and bibliographies on prediction of individual heat transfer coefficients for evaporating films on/in horizontal/vertical tubes, can be found in other publications (21, 22, 24–27).

The limiting step in heat transfer is usually the thermal resistance from the liquor itself and/or deposit formation on the liquor side (the last two terms in the previous equation.) On the heating medium side, the heat transfer coefficients are usually for condensation and are therefore substantially larger than those on the liquor side, which are for boiling. The conduction resistance of the tube wall is usually small (but this is not necessarily true of the resistance of deposits that accumulate on the tube wall).

Deposits typically accumulate more on the boiling side than the condensing side. To determine coefficients for systems with substantial surface deposition, experimental data on that particular system is usually necessary.

Heat-sensitive products can break down to insoluble forms that deposit on the surface and inhibit heat transfer. For example, some soluble proteins, when heated, convert to an insoluble form (18). Change in the heat transfer characteristics of the tube surface can also be induced by corrosion.

The liquor can be on either the inside or the outside of the tubes, depending on the physical and chemical characteristics of the materials involved. Considerations include convenience in cleaning deposits from the heat transfer surface, the heat transfer characteristics of the fluids involved, and fluid velocities required for efficient heat transfer or prevention of scale deposition.

A useful table of criteria and data for the rapid design and selection of evaporators is available (10).

Natural circulation evaporators have overall coefficients of the order of $1.1\text{--}3.4 \text{ kW}/(\text{m}^2\text{K}) = 200\text{--}600 \text{ Btu}/(\text{h ft}^2\text{F})$. Adding forced circulation may raise this to the order of $11 \text{ kW}/(\text{m}^2\text{K}) = 2000 \text{ Btu}/(\text{h ft}^2\text{F})$. In agitated-film units, for Newtonian liquids with viscosity of the order of water, coefficients of the order of $2.3 \text{ kW}/(\text{m}^2\text{K}) = 400 \text{ Btu}/(\text{h ft}^2\text{F})$ may be obtained. As the viscosity increases to $10 \text{ Newton sec}/\text{m}^2 = 10,000 \text{ centiPoise}$, the coefficient will drop to the order of $0.7 \text{ kW}/(\text{m}^2\text{K}) = 120 \text{ Btu}/(\text{h ft}^2\text{F})$. More extensive listings of overall coefficients for evaporators may be found in the literature (1, 8, 10, 28).

The heating medium must be at a higher temperature than the liquor, and the resultant temperature driving force must be sufficiently large that excessive area for transfer is not required. One means of increasing the temperature driving force for a heating medium at a given temperature is to reduce the pressure of the liquor side to decrease the boiling temperature. This is a common device in evaporation, and is often accomplished with a steam-jet ejector. Design (and cost) of such ejectors is detailed in the literature (29).

If the overhead vapor is water and the heating medium is steam, the vapor generated is usually comparable in amount and quality to the heating steam used, but is at a lower pressure because the heating steam must be at a higher temperature (therefore, pressure) than the liquor in order to furnish an adequate temperature driving force for heat transfer. A logical question is whether or not to attempt to recover the latent heat in the vapor generated.

The condensing temperature of the vapor does not usually furnish an appropriate temperature difference to permit transferring heat to the liquor (except, perhaps, a small part to sensible heat of the incoming liquor). However, compressing the vapor will raise both its temperature and its condensing temperature, permitting the vapor to be used to transfer its heat of vaporization/condensation to the liquor with consequent recovery of thermal energy.

Unfortunately, the work required for such compression is high-quality (and therefore, expensive) mechanical energy that ends up as low-quality thermal energy. Either thermocompression or mechanical compression may supply the required mechanical energy. Thermocompres-

sion is accomplished by means of high-pressure steam in an ejector system [for design and cost of ejectors see (29)], while mechanical compression is usually done by a centrifugal compressor (1).

An alternative scheme is to split the evaporation process into stages (in different vessels), commonly referred to as *effects*, where the flow of liquor may be in the same direction, the backward direction, or normal to the flow of vapor (1, 9). In such a scheme, the vapor generated in a given effect is used to boil the liquid in a different effect where a proper temperature driving force exists. In multiple-effect evaporation, one exchanges savings in steam costs for increased capital investment in equipment.

Pennink (30) notes that the optimum is usually 3 or 4 effects in a 50,000 lb/h system and 7 to 8 effects in very large systems. Ramakrishna (31) details a shortcut method to estimate the optimum number of effects for multi-effect evaporation, and Ulrich (10) gives a shortcut algorithm for the design of multiple-effect evaporators. A sample calculation can be found in Schilt (15). Cole (18) gives specific steam consumption and minimum evaporation rates for single and multiple-effect evaporators with and without steam-jet thermocompression, as well as data on mechanical vapor recompression cost per ton of water evaporated.

For those who wish to pursue more detailed design, a good starting point for mechanical design of heat exchange equipment is Azbel (9), who also discusses alternative materials of construction. For general discussion of evaporation as well as insight into safety/environmental considerations, see a report from the U.S. Environmental Protection Agency (32). This document discusses failure analysis as applied to evaporators for treatment of effluent from the metal finishing industry. Other useful references, which have extensive bibliographies, are Rubin et al. (33), Knudsen et al. (34), Chisholm (35), and Taborek et al. (36). The continuing series from the American Society of Mechanical Engineers, as exemplified by Shah (37), contains additional information.

COSTS ASSOCIATED WITH EVAPORATORS

The two major costs associated with evaporators, as with any process equipment, are capital investment and operating costs. The best estimate of the installed cost of evaporation systems is, of course, a firm bid from a vendor. The installed cost, however, can be estimated based on the heat transfer surface area, as in Peters and Timmerhaus (38). Costs taken from published references

must be adjusted for changes subsequent to the time of publication. To do this, one may use an index such as the Marshall and Swift all-industry index. The value of this index is published each month in *Chemical Engineering*, a McGraw-Hill publication. Further information on the use of this and other cost indices as well as their histories are available, for example, in Peters and Timmerhaus (38) and Ulrich (10). Variation of purchased evaporator costs with material of construction and pressure can also be found in Ulrich (10).

A chart to estimate the costs of ejectors for thermocompression has been developed (29). Approximate costs of compressors for mechanical vapor recompression also can be found (38–40). In addition, these publications contain details of cost estimation for heat exchangers. For more detailed estimation of cost of shell-and-tube exchangers, see Purohit (41–43). Plate-and-frame and spiral-plate heat exchanger costs can be estimated using Kumana (44).

Operating expenses can be approximated using published techniques (10, 38). These are mainly useful for preliminary cost estimates only. Such items as raw materials, operating labor, utilities, supervisory expenses, maintenance and repairs, etc., may vary greatly depending on the specific process in question.

OPERATION AND CONTROL OF EVAPORATORS

Many of the problems in operation and control of a given evaporator system will be specific to the application. However, all systems need to answer such questions as how to evaluate performance, how best to schedule periodic *boil outs* (cleaning), how to measure and control variables typified by temperature, pressure, fluid level, fluid flow rate, composition, etc., and how to detect faults in evaporator operation quickly and efficiently (45, 46).

At one time, the American Institute of Chemical Engineers issued a guide to performance testing of evaporators (47). The Instrument Society of America issues a book-length guide for the operation and control of evaporators (2), which covers, among other topics, such operational considerations as the optimum use of boil outs. Instrumentation is covered in detail, including variables, the choice of measurement and measurement method, and both design and implementation of the control system including digital techniques. This work contains both chapter bibliographies and a general bibliography.

Operation of an evaporator for minimum cost of production involves scheduling cleaning cycles to remove scale or deposits. Minimizing costs requires the balancing of increased evaporation rate against out-of-service time. Shutdown involves costs associated not only with cleaning, but emptying and refilling as well. The crux of such optimization is the function used to describe the evolution of scale formation with time.

EUROPEAN AGENCY FOR THE EVALUATION OF MEDICINAL PRODUCTS (EMA)

David M. Jacobs

David M. Jacobs Consulting, Basel, Switzerland

INTRODUCTION

History of the European Union

After the Second World War, the idea of a “United States of Europe” was promulgated and in 1957, the Treaty of Rome was signed instituting the European Economic Community (EEC) between six countries (Germany, Belgium, France, Italy, Luxembourg, and the Netherlands). In 1973, Ireland, the United Kingdom, (UK) and Denmark joined the EEC. In 1974, heads of state and government decided that a European Parliament should be elected by direct universal suffrage and that it would meet regularly as the European Council (EC) to deal with community affairs and political cooperation. Greece acceded to the EC in 1981, and Spain and Portugal joined in 1986. In 1992, the 12 Foreign Affairs Ministers signed the Maastricht Treaty instituting the European Union (EU), which also included the four freedoms of labor, capital, goods, and services. Finally, Austria, Finland, and Sweden joined the EU in 1995. The Treaty of Amsterdam, which entered into force on May 1, 1999, made further institutional changes such that no draft text can become law without the formal agreement of both the European Parliament and the Council. Thus, the EU now consists of 15 member states, each of which has its own national government and legislative bodies.

The EEC has three important powers:

1. It adopts “European laws” that apply in the 15 countries (“directives” and “regulations”).
2. It disposes of a budget to finance certain programs carried out in its member states.
3. It signs international agreements on cooperation or trade.

All these decisions are taken by common institutions sitting in Brussels, Strasbourg, and Luxembourg. Since 1974, the EC has brought together heads of state and government of the 15 member states, as well as the president of the Commission, to set key guidelines and political goals and to arbitrate on questions for which agreement has not been found within the EU Council of

Ministers. Each member country presides over the Council for a six-month period.

EUROPEAN UNION INSTITUTIONS AND LEGISLATIVE INSTRUMENTS

The European Commission, representing the Community’s interests, draws up common projects and, after a decision has been taken by the EU Council of Ministers, sees that they are properly implemented. It is directed by 20 commissioners and is assisted in its work by a permanent staff of 17,000, most of who are based in Brussels. It is independent of the governments but is subject to control of the European Parliament. It implements common policies and negotiates international agreements. It may bring an action before the European Court of Justice should Community laws not be respected by the member states. It is here, within the Pharmaceuticals and Cosmetics Unit of the Directorate-General for Enterprise (formerly the Directorate-General for Industry, DG III), that European legislation on medicines is drawn up and implemented.

The European Parliament is made up of 626 deputies who are elected by direct universal suffrage every 5 years. It examines all proposals for European directives and regulations, which it may accept, modify, or refuse. It supervises the work of the European Commission, which it can dismiss with a motion of censure, and it votes the annual Community budget.

The EU Council of Ministers meets in order to adopt proposed European directives and regulations in light of the advice given by the European Parliament. The ministers convene depending on the subject that the Council is dealing with and according to their areas of competency (i.e., the ministers of health of the 15 member states are present for a Council dealing with questions of drug regulation or health.) The country presiding over the EC holds the presidency of the EU Council of Ministers. Due to the principle of subsidiarity, Community legislation is only introduced on points of common interest and in order to further the aim of a balanced and dynamic Europe.

The Council of Ministers can adopt several types of legislation, which are more or less restrictive:

- “Regulations” are binding and directly applicable to all citizens.
- “Directives” are binding on all citizens but indirectly (i.e., after they have been “transposed” into the laws of each country).
- “Decisions” are binding and directly applicable but only to the institutions, bodies, businesses, or citizens specifically named.
- “Recommendations,” “advisory opinions,” and “resolutions” are consultative or guidance texts addressed to the states.

EU LEGISLATION FOR PHARMACEUTICAL AND VETERINARY PRODUCTS

The foundation of European pharmaceutical legislation is Directive 65/65/EEC (1), which when promulgated in 1965, applied only to the initial six member states. In this directive, the definition of a medicinal product is given and the data required to obtain approval is described. This original directive is continually updated, amended, and supplemented with subsequent legislation, but remains the basis of pharmaceutical legislation.

Ten years following the first direction, three new directives sought to further promote public health and the free movement of medicinal products within the community. Directive 75/318/EEC (2) set analytical, pharmacotoxicological, and clinical standards for testing proprietary medicinal products. Directive 75/319/EEC (3) established the Committee for Proprietary Medicinal Products (CPMP) and its partial mutual recognition procedure, while Directive 75/320/EEC (4) set up a Pharmaceutical Committee to examine problems in implementing the pharmaceutical directives.

In the years that followed, cooperation between national health authorities at EU level was further encouraged. Two Directives, 83/570/EEC (5) and 87/22/EEC (6), set up the Multistate procedure and the Concertation procedure. These procedures provided a mechanism for exchange of information on all aspects of product licensing between member states and made it easier for national licensing authorities to recognize each other's decisions. In the Concertation procedure, the CPMP was charged with forming an opinion on the feasibility of an application, which, however, was not binding on the member states' national authorities. The Multistate procedure was based on the principle of

recognition of an approval in one member state by the national health authorities in other member states.

The European Agency for the Evaluation of Medicinal Products (EMA) was established by Council Regulation (EEC) No 2309/93 (7) of July 22, 1993, with London chosen as its seat by decision of the Council on October 29, 1993. It began operation on February 1, 1995. Regulation 2309/93 also established the legal basis for a single community-wide centralized procedure for the approval of medicinal and veterinary products.

Simultaneously, Directive 93/39/EEC (8) amended Directives 65/65/EEC (1), 75/318/EEC (2), and 75/319/EEC (3) and established the Decentralized Procedure (commonly known as the Mutual Recognition Procedure).

THE EMA

Mission

The Mission of the EMA is to contribute to the protection and promotion of public and animal health by:

- Mobilizing scientific resources from throughout the EU to provide high quality evaluation of medicinal products, to advise on research and development programs, and to provide useful and clear information to users and health professionals

- Developing efficient and transparent procedures to allow timely access by users to innovative medicines through a single European marketing authorization

- Controlling the safety of medicines for humans and animals, in particular through a pharmacovigilance network and the establishment of safe limits for residues in food-producing animals

Structure

The European system is based on cooperation between the national health authorities of the member states and the EMA. The EMA acts as a focal point of a network that coordinates the scientific resources made available by the member states. This partnership between the EMA, national health authorities, and the EU institutions is crucial to the functioning of the European authorization procedures.

A Management Board supervises the EMA, while its scientific activities are largely carried out through its two scientific committees and their working parties. The Board, scientific committees, and their working parties are supported by the EMA secretariat, headed by an Executive Director.

The Management Board is made up of two representatives from each member state, from the European Parliament and from the European Commission. Representatives of Iceland and Norway, who are members of the European Economic Area (EEA) but not of the EU, also attend meetings of the Board. As of January 1, 2000, these countries formally joined the EMA. The Management Board appoints the Executive Director, and approves the budget and work program each year. On the recommendation of the European Parliament, it gives discharge to the Executive Director for the implementation of the budget.

The principal scientific bodies of the EMA are the CPMP and the Committee for Veterinary Medicinal Products (CVMP). They are made up of two members from each member state as well as from Norway and Iceland, and are appointed to give independent scientific advice to the EMA. The EMA Secretariat comprises four units: administration, evaluation of medicines for human use, technical coordination, and evaluation of medicines for veterinary use.

The Administration Unit is responsible for carrying out administrative and financial functions to ensure that the Secretariat and staff are able to perform their statutory tasks under satisfactory conditions and thus, has two subsections for personnel, budget and facilities, and for accounting.

The Unit for the Evaluation of Medicines for Human Use is responsible for the following:

- management and follow-up of marketing authorization applications under the centralized procedure;
- postmarketing maintenance of authorized medicinal products;
- management of community referrals and arbitrations arising from the mutual recognition procedure; and
- provision of support to European and international harmonization activities of the CPMP and its working parties.

This unit consists of three subdivisions or sectors: for regulatory affairs and pharmacovigilance, for biotechnology and biologicals, and for new chemical substances.

The Unit for the Evaluation of Medicines for Veterinary Use is responsible for the following:

- management and follow-up of marketing authorization applications under the centralized procedure;
- management of applications for the establishment of maximum limits for residues of veterinary medicinal products that may be permitted in foodstuffs of animal origin;
- postmarketing maintenance of authorized medicinal products;

- management of community referrals and arbitrations arising from the mutual recognition procedure; and
- provision of support to European and international harmonization activities of the CVMP and its working parties.

It has two sectors: for CVMP and veterinary procedures, and for safety of veterinary medicines.

The Technical Coordination Unit is responsible for providing logistical support to both human and veterinary medicine evaluation activities as well as a number of general services to the EMA, including document management, conference services, and information technology support. It has four sectors: for inspections, for document management and publishing, for conference services, and for information technology. The sector for inspections coordinates the work of inspectors, the implementation of mutual recognition agreements, and the monitoring of medicines authorized in the community. It provides the secretariat of the Quality Working Party and coordinates the Agency's quality management program.

EMA Scientific Committees

The CPMP and the CVMP are the scientific committees set up to facilitate the adoption of scientific decisions between member states on the authorization of medicinal products on the scientific criteria of quality, safety, and efficacy.

When working for the EMA, members of the CPMP and CVMP act independently of their nominating member state. The scientific committees are aided by a network of approximately 2300 European experts, nominated by the national competent authorities of the member states on the basis of proven experience in the assessment of medicinal products. Experts may serve on working parties or expert groups of the CPMP or CVMP.

The scientific committee decides the appointment of rapporteurs and corapporteurs, i.e., those members of the CPMP or CVMP who take the lead in reviewing a dossier. The committees are required to ensure that all members undertake the role of rapporteur or corapporteur. Compensation is provided to national competent authorities for the services provided by committee members or European experts at the specific request of the agency.

THE CPMP AND THE EVALUATION OF MEDICINAL PRODUCTS FOR HUMAN USE

A CPMP member acts as rapporteur or corapporteur for centralized procedures and the CPMP gives an official

opinion on whether an application for marketing is approvable or not. The EMA is intimately involved in the management of this procedure up to the issue of the marketing authorization. The EMA's involvement also includes preparation of the CPMP opinion in all 11 official EU languages. Quality management standards have been implemented for the preparation of scientific advice and opinions, and a tracking system throughout the life cycle of centrally authorized products has been developed. Postauthorization, variations, and extensions to the license may be submitted and rapporteurs play a major role with these maintenance activities. There is also ongoing activity with regard to adverse drug reaction (ADR) reporting, periodic safety update reports (PSURs), and other follow-up measures. Rapporteurs and corapporteurs are particularly involved in urgent safety restriction procedures.

Pharmaceutical sponsors may seek advice on their development programs from the CPMP. The CPMP has set up a scientific advice review group to strengthen and widen CPMP input and to guarantee the availability of proper expertise. A standard operating procedure for the giving of scientific advice by the CPMP for innovator medicinal products has been adopted.

Working Parties

The CPMP and CVMP each have four working parties, as well as a joint CPMP/CVMP Quality Working Party. There is also an EMA working party on Herbal Medicinal Products.

The CPMP working parties are concerned with biotechnology, efficacy, safety, and pharmacovigilance. The CVMP working parties are concerned with safety of residues, immunological veterinary products, veterinary pharmacovigilance, and efficacy.

These working parties produce position papers, points to consider, notes for guidance, and joint CPMP/CVMP/International Conference on Harmonization (ICH) Guidelines that provide up-to-date scientific opinions on matters of current interest to all member states and pharmaceutical and veterinary manufacturers.

Biotechnology working party

This working party considers aspects of the manufacture and control of biotechnological and biological medicinal products and is also involved in the provision of scientific advice. For example, workshops were held recently on the application of assays for markers of transmissible spongiform encephalopathies (TSE) and on the potential risk of transmitting new variant Creutzfeldt–Jakob Disease (nv-CJD) through plasma-derived medicinal products.

Efficacy working party

Clinical trial methodology and guidelines for special disease-related therapeutic fields are discussed in this party. In cooperation with other working parties, guidance on modified release oral and transdermal dosage forms, on pharmacokinetics, and on clinical investigation of new vaccines, gene therapy, and cell-cultured influenza vaccines has been given.

Pharmacovigilance working party

This working party considers safety-related issues at the request of both the CPMP and national authorities, resulting in the harmonization of the summary of product characteristics and package leaflets of marketed products. Regular video conferences are held with the U.S. Food and Drug Administration (U.S. FDA) to discuss issues of mutual interest. A pilot project was started for the electronic transmission of individual case safety reports with a restricted number of participants from national authorities and marketing authorization holders.

Safety working party

Preclinical and safety issues are discussed, and in cooperation with the Biotechnology Working Party, a note for guidance on the quality, preclinical, and clinical aspects of gene transfer products was produced recently.

Ad hoc and other groups

Ad hoc groups on excipients, Lipodystrophy, and antiretroviral medicinal products have been formed. A multidisciplinary group has been set up to evaluate medicinal products containing thiomersal with a view to limiting exposure to mercury and organomercurial compounds.

Cooperation with Competent Authorities

European Monitoring Centre for Drugs and Drug Addiction (EMCDDA)

The EMA has supported the development of guidelines on risk assessment of new synthetic drugs.

International Conference on Harmonization (ICH and VICH)

The EMA, as one of the six partners in the ICH process, is intimately involved in production and update of ICH guidelines. The Unit for the Evaluation of Medicinal Products for Human Use supports the Steering Committee, the EU topic leaders, the CPMP, and the various working parties in the preparation, review, and administration of ICH guidelines. Similarly, since establishment of the VICH

in 1996, the Unit for Evaluation of Veterinary Medicinal Products supports the Steering Committee and the CVMP as well as the various working parties in this initiative.

Central and Eastern Europe

Many central and eastern European countries (CEEC) are candidates for accession to the EU. The candidates are Bulgaria, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Romania, Slovakia, Slovenia, and Cyprus. In order to help pharmaceutical registration authorities in these countries prepare for EU membership, a Collaborative Agreement of Drug Regulatory Authorities of European Union Associated Countries (CADREAC) was formed. In addition to this agreement, a simplified procedure for the recognition of centrally authorized medicinal products by the national authorities of CEEC was established. The procedure is optional and is initiated at the request of the marketing authorization holder in the EU.

In addition, under the auspices of a pharmaceutical Pan-European Regulatory Forum (PERF) set up by the European Commission, the EMA administers and provides executive assistance to CEEC and EU regulators in the conduct of working groups and training sessions in order to facilitate the adoption of common technical requirements. Topics include the implementation of Community legislation, pharmacovigilance, and the assessment of dossiers for marketing authorization for quality safety and efficacy.

Meanwhile, to help eliminate technical barriers to pharmaceutical trade with the CEECs, protocols to permit mutual recognition of good manufacturing practice compliance for medicinal products are being negotiated.

THE CVMP AND THE EVALUATION OF MEDICINAL PRODUCTS FOR VETERINARY USE

The CVMP operates in a similar fashion to the CPMP and is heavily involved in the review of centralized procedures for veterinary products. The CVMP has developed a broad range of new guidelines to assist applicants on topics related to research and development and for which no guidance existed previously.

The Unit for the Evaluation of Medicinal Products for Veterinary Use has also been involved in the PERF initiative as well as other activities related to implementation of Community legislation and the quality of medicinal products.

When the EMA opened in January 1995, more than 600 "old" substances remained for which maximum residue limits (MRLs) had to be established. The

assessment of these products was completed before the January 2000 deadline.

Veterinary Working Parties

Similarly to the CPMP Working Parties, the Efficacy, Safety of Residues, Immunologicals, and Pharmacovigilance Working Parties develop guidelines for the testing and reporting requirements of studies for products for veterinary use.

INSTITUTIONAL PARTNERS

The major contact within the services of the European Commission is the Pharmaceuticals and Cosmetics Unit of the Directorate-General for Enterprise; however, there is also continued exchange of information with the Directorate-General for Health and Consumer Protection. Other contacts include the Directorate-General for Research and the Joint Research Center.

European Technical Office for Medicinal Products (ETOMP)

The European Commission Joint Research Center has established a technical office at the EMA responsible for the management of a telecommunications network and other computer technologies to facilitate the dissemination of information on medicinal products. It also manages the EMA Internet website. A new mechanism for the secure exchange of documents through the Internet has been put in place to facilitate, among other things, the transmission of individual case safety reports within the pilot project on pharmacovigilance between EMA, national authorities, and the pharmaceutical industry.

The European Union drug regulatory authorities' network (EudraNet) is an internetworking service provided to EU medicinal regulatory authorities in collaboration with the European Commission Directorate-General for Industry. Part of the EudraNet is accessible to industry and the general public.

Joint Interpreting and Conference Service (JICS)

The JICS of the European Commission serves the institutions of the EU, as well as the decentralized agencies and bodies located in EU member states. A representative of the JICS is based at the EMA to coordinate translation and conference needs. A glossary of specialized and technical EMA terms to assist interpreters at EMA meetings is being developed.

The European Department for the Quality of Medicines (EDQM)

European Pharmacopoeia (EP)

The EP was founded by Belgium, France, Germany, Italy, Luxembourg, Netherlands, Switzerland, and the United Kingdom in 1964, under a Council of Europe Convention, to help standardize their national pharmacopoeias. The EP now has 26 signatories (15 member states, the European community, and 10 other European countries). Its monographs have force of law, replacing the old national pharmacopoeias. Directive 75/318/EEC requires EU pharmaceutical manufacturers to use these monographs when compiling marketing authorization applications. The EMA participates in the work of the EP Commission as part of the EU delegation.

European Network of Official Medicines Control Laboratories (OMCL)

This is a joint project between the EU and the Council of Europe to allow the coordination of laboratory controls between the EU and EFTA members. In 1999, a contract was signed between the EMA and the EDQM to organize sampling and testing of centrally authorized medicinal products by the OMCL network.

EUROPEAN APPROVAL PROCEDURES

There are two European procedures for obtaining a marketing authorization in more than one country belonging to the EU. These are the Centralized Procedure and the Decentralized or Mutual Recognition Procedure.

Centralized Procedure

The Centralized Procedure must be used for biotechnology products and can be used for so-called high technology products as well as for new active pharmaceutical ingredients (i.e., products that have never before been approved for marketing). The Centralized Procedure is laid down in Council Regulation (EEC) N° 2309/93 (7) and Directive 93/41/EEC (9).

In the Centralized Procedure, one license to market the drug in the entire EU is issued and in principle there is only one evaluation of the dossier. In fact, both a rapporteur and corapporteur are appointed, and each assesses the dossier with its own team. The rapporteur and corapporteur are members of the CPMP who are assigned to a particular

dossier by the CPMP. Each member is obliged to act as rapporteur or corapporteur.

Before submission of the dossier, the Sponsor Company contacts the CPMP or CVMP to announce its intention to make a registration submission and to request appointment of a rapporteur. If, as is usually the case, the Sponsor has had contact with national health authorities, it may request that a particular CPMP or CVMP member be appointed as rapporteur. The CPMP/CVMP is not obliged to follow this request, but in many cases either the rapporteur or the corapporteur is the CPMP/CVMP member requested.

After submission, the rapporteur and corapporteur have 120 days to perform their review and to write a draft assessment report. The two assessments are then discussed by the parties and a list of outstanding issues is sent to the sponsor, at which point the clock is stopped. When the answers have been received, the rapporteur has another 30 days to finalize the assessment report, which is sent to the CPMP or CVMP. CPMP/CVMP members also receive a copy of Part I of the dossier and may request the full dossier. After a total of 210 days, the CPMP or CVMP delivers an opinion: favorable or unfavorable.

If the opinion is favorable, the second stage of the procedure, the decision-making process, begins. During the decision-making process, the Commission Services check that the marketing authorization complies with community law and turn the agency opinion into a binding decision for all the member states. Should the CPMP decision be unfavorable, the sponsor may appeal and a second CPMP opinion must be prepared within 60 days.

The agency sends the Pharmaceutical Unit of the Commission its opinion in all 11 community languages together with the Summary of Product Characteristics (SPC), the particulars of the manufacturing authorization holder responsible for batch release and of the manufacturer of the active substance, as well as the labeling and package leaflet. The commission has 30 days to prepare a draft decision. During this period, various commission directorates-general are consulted and are able to give their opinions.

The draft decision is then sent to the Standing Committee on Medicinal Products or the Standing Committee on Veterinary Products for their opinions. Should there be detailed opposition from a member state to the draft commission decision, the standing committee can refer it back to the CPMP if the opposition is scientific. If the matter is nonscientific, a vote is taken and the council decision is made on the basis of a qualified majority. Each member state has a different number of votes depending on size and importance, and the majority of votes must be in favor. If there is no opposition within 30 days, the draft decision is forwarded to the Commission

Secretariat-General for adoption, enabling the Commissioner for Enterprise and the Information Society to issue the final decision. The final decision is published in the Official Journal of the European Communities.

Decentralized Procedure

The Decentralized Procedure is made on the basis of mutual recognition. Council Directive 93/39/EEC (8) has been implemented in all member states in accordance with Directives 65/65/EEC (1) and 75/319/EEC (3). The sponsor makes a submission to the national health authority of one member state, with a request to assess the dossier for mutual recognition. Within 210 days, the so-called Reference Member State (RMS) must approve the application, prepare an assessment report, and agree on an SPC. The clock may be stopped to obtain further information during this time.

The mutual recognition submission can then be made to any number of the other member states, and the RMS sends a copy of the assessment report to the concerned member states (CMS). Within 90 days, member states must raise serious objections and if there are none, each CMS issues a national marketing authorization with an identical SPC.

To facilitate the mutual recognition procedure, a Mutual Recognition Facilitation Group (MRFG) and a Veterinary Mutual Recognition Facilitation Group have been set up, although this was not foreseen in the original directive. These groups meet one day before each CPMP/CVMP meeting. The objections raised are discussed within the group and the RMS tries to reach agreement on the approval possibilities of the dossier and the most appropriate labeling. If necessary, breakout sessions with the sponsor can be held to finalize labeling details.

Should no agreement be reached within the MRFG/VMRFG, the matter is sent to the CPMP/CVMP for an opinion. Thereafter, the procedure is similar to that during the centralized procedure—the end result being a commission decision after which national licenses must be issued within 30 days.

Referrals and Arbitration

A sponsor company or a national authority may make referrals to the EMA under Article 10 of Directive 75/319/EEC, in order to harmonize the summary of product characteristics in all member states for products previously approved under national legislation.

Similarly, where there are public health concerns as a result of pharmacovigilance data, nationally authorized products or products authorized by the mutual recognition procedure may be referred under Articles 12 or 15 of Directive 75/319/EEC. The CPMP/CVMP gives an opinion on variation, suspension, or withdrawal of the marketing authorization in such cases.

EQUIPMENT CLEANING

Destin A. LeBlanc

Cleaning Validation Technologies, San Antonio, Texas, U.S.A.

INTRODUCTION

REGULATORY BACKGROUND

GMP Issues

Cleaning of process equipment has been part of the good manufacturing practices (GMPs) for pharmaceutical manufacturing for many years (1, 2). This has included recommendations for written procedures, cleaning logs, and appropriate design of equipment to facilitate cleaning. Good cleaning practices are necessary to preserve the safety and efficacy of the manufactured drugs and drug products. Possible consequences of inadequate cleaning include cross-contamination (the presence of one drug active in another drug product at an unacceptable level), the presence of foreign material (e.g., a cleaning agent, solvent, or excipient from another drug product), the presence of microbial contamination (numbers and/or species of microbes), or the presence of endotoxins (particularly in parenteral or ophthalmic products). The presence of such contaminants in a drug product may pose safety problems depending on the level of the contaminant. Such contaminants may also affect the efficacy of a drug product; effects could include modifying the bioavailability of the active, the dissolution time of tablets, or the stability of the finished drug. Needless to say, failing to follow GMPs relating to cleaning processes also renders the product “adulterated” and subject to regulatory action.

Expectation of Validation

What is new since about 1990 is the regulatory expectation that certain cleaning processes in pharmaceutical manufacturing be validated. Validation of cleaning processes had been discussed in numerous articles prior to that time (3, 4). However, issues with drug product contamination due to poorly controlled cleaning processes (5), culminating in the Barr Laboratories decision (6), brought this issue to the forefront and clearly established the FDA’s authority to require the validation of cleaning processes. As cleaning is a process, the principles of process

validation apply to the cleaning process. The Barr decision was followed soon by FDA cleaning validation guidance documents in 1992 (7) and 1993 (8). In 1996, the FDA proposed amendments to the GMPs which clearly defined (if approved) validation of cleaning processes as a GMP requirement (9). The U.S. FDA took the lead in requiring validation of cleaning processes, and other agencies also issued similar requirements. This includes the Pharmaceutical Inspection Cooperation Scheme (PIC/S) document PR-1-99 (10), the Draft Annex 15 to the EU GMPs (11), and the Canadian Therapeutic Products Programme “Cleaning Validation Guidelines” (12). Although the initial emphasis was on cleaning validation related to finished drug products, additional guideline documents clarified that cleaning validation should be considered for active pharmaceutical ingredients (13, 14) and for pharmaceutical excipients (15).

Applicability of Cleaning Validation

It should be noted that these cleaning validation requirements apply only to *critical* cleaning processes. Although GMPs require the cleaning of (and cleaning SOPs for) floors, walls, and the outside of process vessels, such processes are not considered critical cleaning processes. The processes that are critical generally include processes for cleaning product-contact surfaces of equipment or utensils. It is these product-contact surfaces that have the possibility of *directly* contaminating the next product made in the same equipment. In addition, the cleaning of nonproduct-contact surfaces that could reasonably *indirectly* contaminate subsequently manufactured products should also be considered for cleaning validation. For example, some companies have, either on their own or because of regulatory requirements, validated the cleaning of internal surfaces of lyophilizers used for production. On the other hand, validation of cleaning between lots of the same product is not necessarily a requirement (16). This is based on the fact that cross-contamination of the active is not an issue. However, other concerns such as contamination with degradation products, with cleaning agent residues, or with microorganisms may suggest that such cleaning is critical, and therefore should be validated.

CLEANING PROCESSES

The overall cleaning process comprises the soiled equipment, a cleaning method with the associated cleaning equipment, a cleaning agent(s), and process parameters (time, temperature, etc.). These factors should all be captured in a cleaning standard operating procedure (SOP).

Equipment Design

As regards the equipment to be cleaned, this depends on both the equipment itself and the residues to be removed. Ideally the equipment to be cleaned has been designed with cleaning in mind. Design characteristics may be different for manual versus automated cleaning. The equipment design may also affect the extent of disassembly of the equipment as part of the cleaning process. Design characteristics that help maximize cleaning include minimizing deadlegs, minimizing cracks and crevices where soils can be trapped, improving accessibility of the cleaning solution to difficult-to-clean portions of the equipment, and providing adequate drainage. Materials of construction should be selected for the equipment based on the expected cleaning process; such materials may affect both chemical (such as acids, alkalis, and solvents) and physical (such as temperature) compatibility. Although it is difficult to cover all the possibilities because of the varieties of equipment to be cleaned, the principle is the same—the selection of the cleaning process will be limited by the original equipment design (except to the extent that such designs can be modified).

Cleaning Methods

Although cleaning methods are sometimes divided into clean-in-place (CIP) and clean-out-of-place (COP) applications, it may be more useful to consider two significant features of cleaning methods to provide broad categorizations of cleaning processes.

Extent of automation

One factor involves the extent of automation. At one extreme of the “automation” continuum is the fully automatic process—no operator intervention is required for preparation of the cleaning solution, for the cleaning cycle, or for any disassembly or reassembly. The only operator requirement might be pushing a button at the beginning of a cycle, recording the cleaning process in the cleaning log book, and perhaps a visual examination as

part of the monitoring procedure at the end of cleaning (and/or before the manufacture of the next product). At the other extreme is the fully manual process. The operator is required for preparation of the cleaning solution, for isolating the system to be cleaned, for applying the cleaning solution, perhaps for applying mechanical action through brushes or wipers, for rinsing the system, and for monitoring process parameters (including the timing of all events). It should be clear that in between these two extremes are various semiautomated processes, which could cover a broad continuum.

Extent of disassembly

A second continuum for cleaning processes involves the degree of disassembly (and consequent reassembly). At one extreme is equipment that requires no disassembly at all (true “clean-in-place”). At the other extreme is equipment that requires disassembly of each component part for cleaning. Disassembly (and reassembly) is preferably avoided for several reasons, including the time it adds to the overall cleaning process (equipment downtime), the concern over damage to the equipment because of stresses during the disassembly/reassembly process, and the concern over incorrect reassembly. However, it should be recognized that there are situations in which partial or complete disassembly of equipment might be required. This includes the removal of filters prior to cleaning, or the opening of a process vessel for placement of a spray device of a portable CIP system into the vessel.

Simplification of cleaning processes

Design of a cleaning process must be taken into consideration not only the nature of the process itself but also the engineering design of the equipment to be cleaned, the various products manufactured in the equipment (such products become “soils” to be cleaned at the end of manufacturing), and the cleaning process parameters (discussed in more detail later). In many pharmaceutical facilities, the objective is to make the process as simple and universal as possible so that one cleaning SOP can be used either for all manufactured products made in the same equipment or for all equipment cleaned in the same process. This simplifies documentation and training and may (because of grouping or bracketing strategies) simplify validation.

Cleaning process steps

The general steps or stages of most cleaning processes involve the following:

Disassembly and isolation: This involves preparation of the equipment for application of the cleaning

solution(s). Disassembly may involve complete disassembly for washing individual parts elsewhere, or may involve partial disassembly, such as removal of filters for separate cleaning elsewhere. The preferred technique for cleaning is to isolate the equipment (or parts thereof) and then clean the entire isolated portion. In a validated process, it is difficult to clean only one portion of a piece of equipment without isolating it (for example, trying to clean a storage vessel only to the level of product in the vessel; the entire vessel, including the vessel dome, should be cleaned).

Prewashing (or prerinsing): In aqueous cleaning, this involves flushing all parts of the system with water (usually at ambient temperature) to physically remove soils that can be readily removed by a flowing water stream. The purpose of the prewash is to minimize soils on the surface for the cleaning step. In this manner, the action of those cleaning agents in the cleaning step are focused on residues that are more tenaciously bound to the surface. In biotechnology manufacture or any manufacture that involves proteinaceous deposits, a second objective of this prewash is to prevent “setting” of those proteinaceous deposits when they are immediately cleaned with a hot water solution. If the cleaning process uses a CIP system, the prewash step is usually a “once through to drain” rather than a recirculating process. The objective is to immediately remove loosely bound soils and discharge them from the equipment rather than to spread them evenly over all equipment surfaces (which would occur to a certain extent in a recirculating system).

Washing: This involves application of the cleaning solution (which may be plain water, but which usually involves some cleaning agent) to all equipment surfaces to effectively remove those soils not removed by the prewash. The washing step may involve continuous application of fresh cleaning solution (such as in a non-recirculating CIP system or in a manual application using a high pressure spray hose), a recirculating application of the cleaning agent in which partially “depleted” cleaning solution is reapplied to surfaces (as in a recirculating CIP system or an automatic machine parts washer), or a static soak of equipment or utensils. The purpose of the washing step is to either dissolve, solubilize, emulsify, suspend, or chemically affect the soils on the surface so they can be readily removed from the equipment either in the washing step (in a non-recirculating process) and/or the rinse step.

Rinsing: The rinsing step is designed to remove both washing solution and associated soluble, solubilized, emulsified, or suspended soils from the equipment. For solvent cleaning, the rinsing solution is usually a fresh application of the same solvent used for the washing step. In aqueous processing, the rinsing solution is usually water. The rinsing step should usually be a non-recirculating

application of the rinsing solution. A general rule of thumb followed for finished product manufacture involving aqueous-based drug products is that the quality of water used in the final rinse should be at least as good as the quality of water used in the manufacture of the next product. The rationale behind this is that any water contaminants in the final rinse left behind on equipment surfaces by the final rinse are identical in quality to water used in manufacturing of the next product. If the drug does not contain water, such as in the manufacture of a synthetic organic active substance, there may be other considerations for the selection of the quality of the final rinse water. A common practice in bulk pharmaceutical manufacture, suitable for most applications where aqueous cleaning is performed, is to use deionized water as a final rinse.

Drying: Drying is an optional step. One factor in whether drying should be done is the time period before the next use of the equipment. Equipment that is to be used immediately (within a few hours) may not have to be dried, particularly if the equipment is effectively drained to minimize any dilution effect of residual rinse water or solvent. However, the effect of residual water on microbial proliferation during extended storage is a significant issue. Options for drying include heated (and optionally filtered) air and the use of a final alcohol/water rinse. The final alcohol/water rinse may also further reduce the bioburden due to the antimicrobial action of the alcohol. This use has to take into consideration the flammability of such a mixture.

Reassembly and storage: These should be part of the cleaning SOP. “Reassembly” may involve removal of temporarily installed cleaning equipment (e.g., the spray device of a portable CIP unit) or reassembly of equipment parts themselves. If the equipment is to be stored for a significant time before reuse, critical elements for storage include whether the equipment is dry, physical protection of equipment from recontamination by use of items such as plastic wrapping, and the room conditions (air quality, temperature, and humidity) where the equipment is stored. Typically it is expected that stored equipment will be tagged as cleaned with an expiration (or “use by”) date. Expiration dates for stored equipment are established based on the possible routes and extent of recontamination during storage. For storage, the focus of regulatory agencies is microbial contamination; however, other types of contamination should also be evaluated.

Automated CIP systems

The discussion of CIP processes deserves special comment because of industry trends to use CIP systems. As used in a broad sense, CIP refers to any system in which the equipment is cleaned with no or minimal disassembly. In a

more narrow sense (and in this sense it is more commonly used now), CIP is used to refer to systems in which one or more spray devices is placed in the equipment to be cleaned. A control unit, comprising a pump, associated valves, and a PLC (programmable logic controller), pumps a cleaning solution from a storage tank through the spray device(s). The spray device(s) is engineered and placed so that solution is either directly sprayed or else sprayed so that the solution cascades down the equipment sidewalls to cover all surfaces of the equipment for effective cleaning. In a non-recirculating CIP system, the cleaning solution passes once through the process vessel and associated piping, and then goes to drain. In a recirculating system, the cleaning solution passes through the process vessel and associated piping and then back to the cleaning solution storage tank. It is then pumped through the spray device again, for multiple passes.

The spray device may be either permanently mounted in the process vessel, or installed for cleaning and then removed for product manufacture. Spray devices may be stationary. Stationary spherical devices, the most common type, are called “spray balls.” Spray balls are usually stainless steel hollow spheres in which holes are drilled. The placement of the holes is designed to provide adequate coverage for the vessel to be cleaned. Stationary spray devices are usually considered “sanitary” because they are self-draining. The other type of spray device is a dynamic (or rotating) spray device. These are similar in principle to a stationary spray device (they are designed to distribute cleaning solution over all surfaces of the process vessel) except that dynamic spray devices will rotate in one or more planes to provide more even distribution of the cleaning solution. Dynamic spray devices also typically operate at high spray pressures, so that the impingement of the cleaning solution on the vessel surfaces provides more mechanical energy to help dislodge residues. Dynamic spray devices are typically not mounted permanently because they are not self-draining (and thus sanitary); however, some newer dynamic devices are claimed to be sanitary.

A key to operation and validation of a spray device is to perform a “coverage” test, such as a “riboflavin test.” Riboflavin is readily water soluble, and also fluoresces under an ultraviolet light. Such a test involves spraying the interior surfaces of the equipment with a dilute solution of riboflavin. A short CIP rinse cycle is then performed using just water in a non-recirculating mode. Following this, the interior surfaces are examined using an ultraviolet light source. If any surfaces fluoresce green, it is an indication that solution coverage in those areas may be inadequate. Poor coverage should require a redesign of the spray device system, either by adding additional spray devices,

using a different spray device, or by drilling additional holes in a stationary spray ball. Such a modified spray system should be retested for adequate coverage. Such riboflavin testing is usually part of the operational qualification (OQ) of the equipment.

Cleaning Agents

Aqueous vs. nonaqueous

In addition to the cleaning method used, the cleaning agents used in the washing step are critical. It should be appreciated that selection of the cleaning method and cleaning agent(s) are somewhat interdependent. Selection of a cleaning method may limit the available cleaning agents that can effectively be used in that process. For example, a CIP process requires a low foaming aqueous cleaning agent, while extent of foam may not be critical for manual cleaning. Cleaning agents may be divided into aqueous and nonaqueous cleaning products. Nonaqueous products are typically solvents, and are more common in cleaning in the bulk manufacture of an active pharmaceutical ingredient (API). Typically, the solvent used for cleaning is the same as that used for manufacture. The cleaning effectiveness depends on the solubility of the residue(s) in the solvent at the temperature of cleaning. Particularly for cleaning of distillation columns, refluxing with a volatile solvent is a common practice for effective cleaning. The trend in the manufacture of APIs is to move away from solvent cleaning to aqueous cleaning. However, it should be recognized that in many cases this is not practical, and even if it is, the aqueous cleaning may be followed by one or more solvent flushes to remove the water from the process vessels.

Types of aqueous cleaning agents

Aqueous processes involve cleaning with water and, optionally, other ingredients to assist in the cleaning process. If aqueous cleaning can be suitably performed, it is preferred over solvent cleaning because of cost issues (including the cost of the solvent as well as the costs of disposal or reclamation of the solvent) and because of environmental issues relating to the use or emissions of solvents. In aqueous processes, the use of water alone should be considered because it eliminates the concerns over having to consider potential contaminants from the cleaning agent during cleaning validation. However, in most cases, the performance characteristics of various aqueous cleaning agents more than overcome the concerns about cleaning agent residues (particularly if the cleaning agents selected are free-rinsing). The successful use of water alone for the washing step depends solely on the

solubility of the residues in water at the temperature of cleaning, and may not typically provide other cleaning mechanisms such as emulsification and dispersion. Therefore, use of water alone may not meet other cleaning objectives such as short processing times.

Another option for aqueous cleaning involves the use of commodity chemicals, including alkalis such as sodium or potassium hydroxide, acids such as phosphoric or citric acid, or sodium hypochlorite solution. These are typically diluted in water at levels of 0.05–1% (w/w), and the resultant solution is typically used at elevated temperatures (45–80°C). Commodity chemicals may provide better cleaning than water alone, and they do so at a relatively inexpensive cost. Residue detection of cleaning agents during validation is relatively straightforward because there is usually only one chemical species to detect from the cleaning agent itself.

A third option for aqueous cleaning is to use a formulated cleaning agent. These formulated products usually contain several functional agents including a surfactant(s), an alkalinity or acidity source, water miscible solvents such as glycol ethers, dispersants such as low-molecular-weight polymers, and various builders such as chelants. The main advantage of such formulated cleaning products is that they are multifunctional because of the variety of components; each component broadens the performance in terms of being applicable on a wider variety of soil types. Well-formulated products thus enable a pharmaceutical manufacturer to use one cleaning agent in one cleaning SOP to effectively clean not only the variety of components in a finished drug product, but also a broader range of finished drugs themselves. It should be noted in the former case that for many (if not most) finished drugs, it is the excipients in the finished drug that are more difficult to clean (as compared to the cleaning of the active ingredient). However, the selection of a formulated cleaning product necessitates that the pharmaceutical manufacturer knows the ingredients in the product, both as a check on the consistency of the formulation over time and to effectively establish residue limits for the cleaning agent.

Basis of selection of cleaning agent

The selection of an aqueous cleaning system is simplified if only water alone, or water and a commodity chemical alone, are used. The cleaning performance can be somewhat predicted based on solubility characteristics (at the appropriate pH) or by consideration of the peptizing performance of alkalinity on protein or the oxidizing action of sodium hypochlorite on denatured protein. In the case of formulated multifunctional cleaning agents, the performance is more difficult to predict based on

chemistry alone, and an acceptable cleaning agent is preferably selected based on experience or on laboratory studies. The selection of cleaning agents is also complicated by the fact that sometimes proper cleaning necessitates the use of two cleaning agents at the same time (a primary cleaning agent and a functional additive of some sort), or by the use of two cleaning agents in succession (for example, the use of an alkaline cleaning product followed by an acidic cleaning product).

Cleaning Parameters

While selection of the cleaning method and cleaning agent(s) is important, equally important are the various parameters to consider in the overall cleaning system. These include cleaning process parameters as well as parameters related to the system actually cleaned. Probably the most important cleaning process parameters are the time of cleaning, the temperature of cleaning, the concentration of the cleaning agent, the water quality, the impingement action of the cleaning solution, and any mixing in the cleaning solution.

Time

Three aspects of time are important to the cleaning process. The first is the time from the end of product manufacture to the beginning of the cleaning process. This is important in validated cleaning because the nature of the soil to be cleaned may change over time. Changes may include the drying of the soil residue (thus possibly making it more difficult to clean) or microbial proliferation (thus increasing the bioburden to be cleaned during the cleaning process). A maximum time between the end of manufacture and the beginning of the cleaning process must be specified, and this maximum time must be considered in the selection of worst case conditions for the validation of cleaning processes. A second aspect of time is the times of the cleaning process steps, as well as the time between steps. This includes specifying the time of the prewash, of the washing step, and of rinsing. These are usually established based on laboratory and scale-up trials in the development of a cleaning SOP. The times between these three steps may be critical; if so a maximum time interval should be specified. For example, in the manual cleaning of larger equipment, the time interval between the washing step and the rinse could be significant if the cleaning agent on the washed part is allowed to dry before the rinsing step starts. Drying after the washing step may redeposit soils and prevent effective rinsing. The expectation for validated cleaning is that the times for the various phases are specified. It is generally unacceptable to specify an open-end time frame such as

“test until clean” (that is, continue repeating the cleaning process until tests indicate the equipment is clean) in a validated process. Such performance is indicative of an uncontrolled cleaning process. The third aspect of time is the time of storage of cleaned equipment. Although recontamination of equipment is generally known to be event related rather than time related, time is known to affect microbial proliferation. For this reason it is expected for validated cleaning processes that an expiration date (or “use by” date) for cleaned equipment be established.

Temperature

A second important process parameter is the temperature, not only of the cleaning solution, but also of the prewash and rinse solution. The solution temperature can significantly affect cleaning performance, including the rate of solubility and the extent of hydrolysis. Control of temperature during cleaning is preferable. However, it should be recognized that consistency is more important than just constancy of temperature. A consistent decrease in temperature (due to the lack of a heat exchanger in a cleaning circuit) may be acceptable for validated cleaning, provided that the decrease in temperature is consistent from one cleaning event to the next. Temperature of the prewash is generally ambient to prevent setting of certain residues at higher temperatures. The temperature of the rinse is probably least critical. However, it should be recognized that the higher temperature of a rinse might facilitate faster rinsing. In addition, if the temperature of a first rinse is significantly lower than the temperature of the cleaning solution, the temperature “shock” may cause a cleaning solution containing emulsified soils to “break,” thus redepositing soils on the equipment surfaces. Temperature should be controlled within reasonable limits, for example, within 5°C of the control point.

Cleaning agent concentration

Cleaning agent concentration should be specified and controlled. Cleaning agent concentration can usually be controlled by diluting based on weight or volume, or by diluting to a known control point, such as to a known conductivity. Within reasonable limits for aqueous cleaning, higher cleaning agent concentrations result in more effective cleaning. Concerns with higher cleaning agent concentration include deleterious effects on equipment and safety issues in manual cleaning.

Water quality

In certain circumstances, water quality can be critical for cleaning performing. If the washing step involves the use of surfactants for cleaning, the presence of hard-water ions (calcium and magnesium) is well known to interfere with

effective detergency. Additionally, in the presence of alkalinity sources (which raise the pH), calcium ions will precipitate as calcium carbonate. Such deposits, if not removed from the equipment surfaces, can contribute to the equipment being judged visually dirty. Some formulated cleaners will contain chelants (such as salts of ethylenediamine tetra-acetic acid) to minimize such possibilities. For most cleaning applications, pharmaceutical manufacturers will also use the same quality of water (Purified Water or Water for Injection) that is used for manufacture of the drug product. Lesser quality water, such as tap water, can be used provided the water quality (both chemical and microbiological) is carefully monitored. In addition, if the tap water quality may vary (due to seasonality or source, for example), the worst-case water conditions must be considered for validation purposes.

Impingement

The impingement of the cleaning solution refers to the physical action of a cleaning solution as it hits the surface from a spray application. Such a spray application may include that from a spray device in a CIP system, or may be from a high-pressure hose spray application. Impingement provides mechanical action to help dislodge residues from surfaces. Such impingement can be beneficial if the dislodged residues can then be suspended, emulsified, or otherwise carried away from the equipment surfaces and removed from the cleaning system. Dislodging residues and just displacing them to another location on equipment surfaces may not prove beneficial. In some circumstances, impingement with a solution containing added cleaning agents may be preferred.

Mixing

Mixing refers to the movement within the cleaning solution itself. With a static application of a cleaning solution, as the soils on the surfaces dissolve, emulsify, or otherwise migrate into the cleaning solution, a concentration gradient of saturated or partially saturated cleaning solution is established near the equipment surfaces. This concentration gradient minimizes the chemical cleaning action. Mixing eliminates this concentration gradient and places fresh cleaning solution (or at least a less saturated cleaning solution) in contact with soils on surfaces. This optimizes the cleaning process. It is desirable that mixing be such that the cleaning solution experiences turbulent flow.

The six parameters discussed above are parameters that usually can be controlled by proper design of the cleaning process. Other parameters that are important for cleaning are things that are controlled more by equipment design or by manufacturing process design. Those characteristics

include the nature of the equipment surfaces, the physical nature of the soil, and the amount of soil.

Nature of the surface

In removing manufactured product soils from equipment, the nature of the surface may also affect the cleaning process. This includes any special factors in the adhesion of the soil to different surfaces. Different surfaces include differences in type, such as stainless steel, glass, and various plastics. Effective removal of soils from all representative surface types is usually considered in a sampling plan for cleaning validation. Different surfaces also include the roughness or smoothness of the surface itself. Although there is controversy on this, as a general rule for most surfaces involved in pharmaceutical manufacturing, smoother surfaces are more easily cleaned. This may be related to the fact that rougher surfaces have cracks or crevices where soils can more easily “hide.” For example, etched glass surfaces are generally more difficult to clean as compared with highly polished glass surfaces. A third factor in considering the nature of the surface is the chemical or physical compatibility of the cleaning solution with the surface itself. The objective in cleaning is to remove the soils and restore the surface to its original condition (or as close to that condition as practical). Two examples of substrate compatibility issues are the repeated use of high levels of hypochlorite on stainless steel (leading to rouge formation) and the use of high levels of aqueous alkalis (sodium or potassium hydroxide) at high temperatures for prolonged periods on glass-lined vessels (leading to etching of the glass surfaces). Other issues might be temperature compatibility of plastics or of gasket materials. Although some deleterious effects may be expected in any cleaning process, the process should be designed to clean effectively and yet keep substrate compatibility issues to a minimum.

Condition of soil

A second factor to consider is the soil condition itself. Three “states” of the soil may be considered—freshly deposited soil, dried soil, and baked-on soils. The difference between the last two is that drying just involves the removal of water without any chemical changes in the soil. Baking usually involves not only the removal of water but also a significant chemical change in the soil. Such chemical changes usually result in the soil being more difficult to remove. For example, drying sugar on a surface may render it slightly more difficult to remove; however, baking it at elevated temperatures will caramelize the sugar and render it extremely difficult to remove. The condition of the soil may change because of manufacturing process conditions, such as product splashing onto a vessel

dome that is steam jacketed and baking onto the surfaces. It also may change because of a time delay after manufacture and before cleaning, allowing the product to dry out. It should be noted that merely drying of certain polymers on surfaces might render them extremely difficult to remove. For example, dried solutions of carboxymethylcellulose (CMC) can be extremely difficult to remove from surfaces.

Although it may be difficult to control the extent of drying or baking in certain processes, these phenomena should be evaluated, and if they do occur, the cleaning process should be designed to remove those soils in the more difficult dried or baked conditions.

Amount of soil

A third factor to consider is the amount of soil on the surface. As a general rule, the greater the amount of soil on the surface, the more difficult the cleaning. For freshly deposited soils, this may not be a serious issue if the bulk of the soil can be readily removed in the prewash. On the other hand, with dried or baked-on soils, the prewash may have little benefit in reducing the amount of soil on the surface. Unfortunately, surfaces that are most likely to have larger amounts of soils (dead legs, cracks, crevices, low flow areas) are also those that are more difficult to clean because of accessibility of the cleaning solution to the surfaces. For cleaning process design purposes, worst cases in soil amounts should be considered.

CLEANING STRATEGIES IN LIGHT OF VALIDATION

Although cleaning processes should be primarily based on what is necessary for good cleaning, they may be modified somewhat based on the regulatory needs for validation. As most pharmaceutical companies will want to validate a cleaning process and not have to do additional significant revalidation work in the near future, this may limit the selection of cleaning agents. As a key part of any validated process is consistency and control, cleaning SOPs for validated processes will also generally have more detail and specificity.

Cleaning for Multiproduct Equipment

Several strategies are possible for cleaning of equipment used to make two or more different products. One option is to optimize a cleaning process for each product made on the equipment. This may mean different cleaning agents for cleaning after each manufactured product, although usually what it means is that the same cleaning agent is

used under different process conditions (such as time and/or cleaning agent concentration). Each manufactured product will have its specific cleaning SOP. Another option is to use only one cleaning process for all products manufactured on that individual piece of equipment. One cleaning SOP (with all process conditions the same) is used for all manufactured products. Such a strategy allows for the possibility of “grouping” or “bracketing” for validation protocol purposes. However, it should be recognized that the decision to use one cleaning SOP for all manufactured products has implications for both cleaning and for validation purposes. A strategy of “one SOP for everything” has advantages for cleaning in terms of simplifying documentation and simplifying training. However, such a strategy can be pursued regardless of whether one adopts grouping strategies for validation or not. Clearly, one can also adopt a hybrid strategy, in which several manufactured products are cleaned with one SOP and another group of products (manufactured on the same equipment) is cleaned with a different SOP.

Cleaning in Campaigns

Cleaning between lots of the same product made successively on the same equipment in a campaign may allow for less aggressive cleaning procedures. The reason is that in such cleaning there is no concern about cross-contamination with an active from a different product. However, there are concerns about cleaning. First is the issue of lot integrity—how much of the active or product from one lot can come along with a different lot and be considered different lots for such purposes as recalls? In addition, while cross-contamination is not an issue, other issues such as contamination from residues of cleaning agents and microbial contamination should also be considered. Another issue in campaigns in which cleaning is minimal is the possibility of degradation product accumulating on the equipment.

VALIDATION ISSUES

IQ/OQ/PQ

Cleaning validation is a type of process validation, and the principles of process validation (17) apply equally to a cleaning process. This includes installation qualification (IQ), operational qualification (OQ), and process or performance qualification (PQ). IQ and OQ should focus on the equipment used for the cleaning process, such as a CIP skid, a spray device, or the monitoring equipment (such as a conductivity probe).

PQ involves performance of the cleaning procedure three consecutive times and evaluating the success of the cleaning procedure, usually by measuring the amount or degree of potential contaminants on the cleaned equipment surfaces. The cleaning SOP should be challenged during the three PQ runs, using (as much as possible) process conditions within the normal ranges that are more likely to induce failure. For example, if the time from the end of manufacture until the beginning of cleaning is specified as a maximum of 12 h, then at least one of the PQ runs should be performed at that maximum time to demonstrate adequate performance.

Cleaning validation is different from other types of process validation in that with cleaning validation both the product cleaned as well as the next product manufactured must be considered. The cleaning SOP is primarily based on what is required to remove the manufactured product. However, the types and acceptable levels of residues following cleaning are also determined by the nature of the next product manufactured in the cleaned equipment. For this reason, cleaning validation is more dependent on what other products are made on the same equipment. Furthermore, the addition of a new product to equipment previously validated for cleaning with multiple manufactured products requires a reevaluation of that previous validation work to determine whether or not the previously validated residue acceptance limits are still applicable in light of a new “next product.”

Residue Limits

Validating a cleaning process includes selecting target residues and setting limits for those residues following the cleaning process. Target residues are selected based on possible residues that can be left after the cleaning process. This requires an understanding of the cleaning process, and may require an investigation into possible degradation products that may occur during the cleaning process. Acceptable levels of those specific residues are based on what could occur should those residues contaminate the subsequently manufactured product (18, 19). Analytical determinations of residues are usually required. In addition to those measurements, it is expected that the equipment will be visually clean. Examination of equipment for visual cleanliness requires training of the observers and may require auxiliary lighting. A visual examination may be supplemented by use of a video camera for recording purposes or by use of a borescope for pipes. In some cases, equipment may be disassembled for visual examination (and optionally for analytical sampling) to determine cleanliness.

Limit in next product

It is important in any discussion of “residue limits” to understand that limits for a cleaning process may be expressed in different ways. This includes the limit of the residue in the subsequently manufactured product, the limit of the residue on the cleaned equipment surfaces, and the limit of the residue in the analyzed sample. These are all related, but they are usually different numbers. For an active ingredient in the cleaning of a finished drug product, the limit in the next product is usually calculated based on application of a safety factor (usually 0.001 or lower) to the minimum daily dose of that active in the maximum daily dose of the subsequently manufactured product. The active or level of active in the subsequently manufactured product is irrelevant unless there is information about unusual deleterious interactions. This calculation is also independent of manufacturing issues such as batch size and equipment surfaces areas, and can be calculated solely on information about the dosing of the two products as follows:

$$L_1 = \frac{\text{MinDA} \times \text{SF}}{\text{MaxDSP}} \quad (1)$$

where L_1 is the limit of the active in the next product, MinDA is the minimum (daily) dose of the active (the target residue), MaxDSP is the maximum (daily) dose of the subsequently manufactured drug product, and SF represents an appropriate safety factor. Care needs to be paid to selection of units; the L_1 limit is usually expressed in $\mu\text{g/g}$ (or ppm).

Limit per surface area

The next limit calculated is usually the limit per equipment surface area. This is calculated based on the limit in the next product, the batch size of the subsequently manufactured product, and the equipment shared surface area. This is expressed as:

$$L_2 = \frac{L_1 \times \text{BS}}{\text{SSA}} \quad (2)$$

where L_2 is the limit per surface area, BS is the batch size, and SSA is the shared surface area. Units should be consistent, and the L_2 limit is usually expressed in units of $\mu\text{g}/\text{cm}^2$.

Limit in analytical sample

The next limit is the limit in the analytical sample. If the sampling method involves swabbing, the surface area swabbed and the amount of diluent used for desorbing the swab must be considered. The limit per swab sample is then calculated as:

$$L_3 = \frac{L_2 \times \text{SA}}{\text{AD}} \quad (3)$$

where L_3 is the limit per analytical sample, SA is the swabbed area, and AD is the amount of diluent for swab elution. Here again units need to be consistent, and the L_3 limit is usually expressed as $\mu\text{g/g}$ or $\mu\text{g/mL}$. It should be clear that the limit in the analytical sample can be manipulated by changing the area sampled (higher areas result in larger limits per analytical sample) or the amount of diluent used (lower amounts result in larger analytical sample limits). If a sampling rinse is used (in place of swabbing), SA effectively becomes the total surface area of the equipment, and AD becomes the volume of solution used for the sampling rinse.

Nondose limits

For residues (such as cleaning agents) that do not have a defined dose, some measure of toxicity, such as an acceptable daily intake (ADI), is used for residue limit purposes. If the subsequently manufactured product is an in vitro diagnostic (IVD), and has no defined dose, then some evaluation of the effects of target residues on the performance or stability of the IVD product should be performed. These nondose factors are used only for the L_1 limit; there are no changes for calculation of L_2 and L_3 limits.

Limits for multiple subsequent products

When a residue limit is to be calculated for a product where there may be more than one subsequently manufactured product, calculations should be made to compare the surface area residue limits (L_2 limits) by using each subsequent product. If the manufacturing order is not to be restricted, the cleaning validation of the first product should be established using the lowest surface area limit.

Sampling Procedures

Sampling procedures for cleaned surfaces can be divided into four types. Direct surface sampling involves a fiberoptic probe (such as a near infrared probe) that is placed directly on the surface. An output is provided as to the type of residue and the level. Such systems are currently in development (20), but are not commercially practical. Swab sampling involves wiping a fixed area of the surface with a premoistened swab. The swabbing procedure is designed to remove any residues from the surface, and the swab is then placed in diluent to desorb the residue from the swab to the diluent. The residue is then measured in the diluent by a suitable analytical technique.

Such swabbing is commonly called “direct surface sampling,” although it clearly is an indirect measure. Rinse sampling involves flushing the equipment surface with a fixed amount of rinse solution (aqueous or solvent), capturing the rinse solution, and then measuring the target residue in the rinse solution. A true sampling rinse is distinct from the final process rinse, and may involve a solution different from that for the process rinse. A fourth sampling procedure is placebo sampling. This involves making a placebo of the subsequently manufactured product in the cleaned equipment. Following manufacture of the placebo, the placebo is sampled and analyzed for the target residue. Any target residue in the placebo would come from the cleaned equipment, and it could be expected that the level present in the placebo would be the level present in any such subsequently manufactured product. Placebo sampling is not widely used because of regulatory concerns related to uniformity of contamination of the placebo from the equipment surfaces and the analytical challenge of finding low levels of residues in placebos.

Analytical Methods

Relationship to target residue

The analytical method selected to measure the target residue must provide a direct measurement of that target residue. When regulatory authorities first began requesting that cleaning be validated, some companies merely tested the rinse water by USP Purified Water specifications to determine if the equipment was clean. The rationale was that the effluent met the same standard as the incoming water. Regulatory authorities (quite rightly) rejected such arguments (because of the possibility of unacceptable levels of potent drugs being present, and because of the possibility that the target residue not being removed in the rinsing procedure), and requested that analytical techniques target the specific residues of concern. However the requirements for analytical methods for residue determination are slightly different from methods for actives level determination in finished product in one important way. For finished product actives determination, a method is required to unequivocally measure the active in the presence of known potential interferences and provide an exact level of the active present. For cleaning validation residue analysis, it is not so as important to know exactly how much residue is present as to know that the amount present is below the acceptance criteria in the validation protocol. For this reason both specific and nonspecific analytical methods can be used for residue detection purposes.

Specificity of methods

Specific methods are preferred because they can more accurately provide information for evaluating potential problems. Because they are designed to eliminate the effects of potential interferences, they can more reliably meet the acceptance criteria. The most common method for residue determination for cleaning validation purposes is the high performance liquid chromatography (HPLC) procedure. In contrast, nonspecific methods such as total organic carbon (TOC) can only provide an upper limit value of the target residue, provided there are no negative interferences (that is, all interferences contribute positively to the analytical response). For TOC, this is usually the case. If the analytical response is treated as if the response comes only from the target residue, then an upper limit calculation of the target residue can be obtained. If such upper limit calculation is below the acceptance criterion, then it is safe to claim that the residue is within acceptance limits. Nonspecific methods such as TOC are more commonly used in biotech manufacture, where proteinaceous actives are readily degraded by the cleaning procedure. In such cases, the TOC values are treated as if the carbon were due solely to the protein active. Actually, some of the carbon may be due to the cleaning agent, and some may be due to the excipients or processing aids.

Validation of methods

It is expected that any analytical method chosen be validated, including an evaluation of specificity, sensitivity (limit of detection and limit of quantitation), accuracy, precision, range, and linearity (21). The range validated is preferably a range around the expected value in the analytical sample. However, it is wise to also include values up to the acceptance limit in the analytical sample.

Sampling/Analytical Method Recovery

The sampling method chosen must be challenged in combination with the analytical procedure to determine the recovery of the sampling method. This is typically a laboratory study involving spiking a model surface with the target residue and performing the sampling procedure on the surface and measuring the residue with the analytical procedure (22). The amount of residue measured is compared to the amount spiked to give a percent recovery. Recoveries of greater than 80% are considered good, but recoveries of greater than 50% are acceptable. As the analytical values have to be transformed by the recovery values, it is desirable to obtain as high a recovery as consistently possible.

MICROBIAL CONTROL ISSUES

Issues in Cleaning

GMPs require that procedures be in place to limit objectionable microorganisms in both nonsterile and sterile drug products. This should be interpreted to include both the number of organisms as well as the type (species) of organism. Protection of subsequently manufactured product from microbial contamination can be accomplished in part by effective cleaning, by a separate sanitizing step, and/or by storage procedures. In many cases effective microbial control is achieved by a good aqueous cleaning process. The conditions of cleaning can either physically remove microbes, or these conditions (hot alkaline or acidic aqueous conditions) can be conducive to the destruction of microbes. The use of hypochlorite for removal of denatured proteins also serves as an effective oxidizing biocide. If cleaning alone does not achieve adequate microbial reduction, the use of either a chemical sanitizer or elevated temperature (steam or hot air) can be considered. Chemical sanitizers include hydrogen peroxide, peracetic acid, quaternary ammonium chlorides, and alcohols; as a general rule phenolic sanitizers are not used for process equipment because of the difficulty of rinsing from equipment surfaces. If the sanitizer leaves a residue, then a final rinse should be considered to reduce that residue to an acceptable level. Acceptable levels of microbes in the cleaned equipment can be established depending on the nature of the subsequently manufactured product. Limits for nonsterile products can be established based on accepted levels of microorganisms in nonsterile products. Such calculations usually result in acceptance levels that are considerably above what can be routinely achieved with good cleaning procedures. Limits for equipment surfaces used for manufacture of terminally sterilized products are usually related to assumptions of the maximum bioburden for product sterilization purposes. Limits for equipment surfaces used for manufacture of aseptically produced products are usually related to assumptions of the maximum bioburden for equipment sterilization purposes.

Issues in Storage

One major regulatory issue in the cleaning of equipment is the possible microbial proliferation due to improper storage, such as in a wet condition or with pools of water. The preferred method for dealing with such concerns is to effectively dry the equipment before prolonged storage. An alternative (but less desirable option) is to include an additional cleaning and/or sanitizing step after storage and

before the next use of the equipment. If this alternative is used, the measurement of both chemical and microbial residues should be performed at the end of this cleaning/sanitizing step.

VALIDATION MAINTENANCE

Once a cleaning process has been appropriately validated, steps should be taken to help insure that the cleaning process remains consistent and in control. Steps that are taken to help assure this include regular monitoring, a change control system, training, and revalidation.

Monitoring

The testing that is done for routine monitoring of the cleaning process should be distinguished from the testing that is part of PQ process qualification. Monitoring tests are usually done on each individual cleaning run. Tests are selected which could be indicative of a cleaning system that is either out of control, or could be trending out of control. Examples of process parameters that could be monitored include the concentration of the diluted cleaning agent, temperature of the cleaning solution, times of various process steps, pressure at a spray device, flow rates, volumes of solutions used, and conductivity of the final rinse water. As these monitoring steps should be part of the cleaning SOP, they should also be performed during the three PQ runs. Some monitoring can give pass/fail information, which clearly indicates the cleaning process is out of control, requiring an investigation and correction of the problem. For example, a higher than specified pressure at a spray device may suggest that spray nozzles were blocked, and that perhaps cleaning coverage was inadequate. This would require an immediate investigation of whether the equipment was adequately cleaned. Such equipment should not be used until a confirmation of adequate cleaning is performed, and the cause of the high pressure corrected. On the other, hand monitoring of the final rinse water conductivity or TOC may show results which do not necessarily suggest that cleaning was inadequate, but rather may display a trend which suggests that cleaning may become inadequate if such a trend continues. This is the value of action and alert limits for monitoring, and of control charts which show trends. It is possible that in certain situations the full range of testing done in the PQ runs would be repeated. However, the value of validation is that consistency has been demonstrated, and the emphasis in monitoring should be tests that might indicate a process change.

Change Control

Validated cleaning processes should be subject to change control. Changes include unplanned and planned changes. Examples of unplanned changes include the failure of a process pump, the clogging of a spray device, and the discontinuance of a cleaning agent by a supplier. The keys to change control are to evaluate the effects of any change, correct the changed item (if possible), implement any increased monitoring as needed, and document the procedure. For example, failure of a pump in a CIP skid may just require a switch of like for like, IQ on the new pump, optionally OQ on the new pump, and proper documentation. Clogging of a spray device may require cleaning of the device and an investigation of the cause of clogging. This should be followed by preventive measures, such as installation of a filter screen to remove material with the potential to clog and some kind of preventive maintenance to regularly clean the screen and inspect the spray device. In both these cases, it may not be necessary to repeat a PQ run. On the other hand, a slight compositional change of the cleaning agent may require laboratory studies to suggest equivalence, followed by one PQ run to confirm equivalence. A change in the manufacturing process itself, and the possible effect of such a change on the cleanability of the equipment, should not be neglected when considering change control for a cleaning process. A change such as increased processing temperature may modify the condition of the soil and, therefore, make it more difficult to clean. In all cases documentation of changes according to a change control SOP is mandatory.

Training

Training operators in the cleaning SOP is an important part of validation maintenance, particularly for manual cleaning methods. Training in a manual method should include a classroom discussion of the method, observation of the SOP being performed by a trained operator, and then demonstration of proficiency by performance of the SOP by the trainee. Training should always follow revision of the SOP, and retraining should follow any deviations that were attributable to operator error.

Revalidation

There are two aspects to revalidation of a previously validated cleaning process. First is revalidation upon any significant change. What is "significant" is a matter of professional judgment. However, a change in cleaning method, such as from manual cleaning to automated

cleaning will generally require revalidation even though the cleaning agent and process parameters are the same. In essence this is not really revalidation but rather validation of a new cleaning process. The other aspect of revalidation is based on the evaluation of the consistency and control of a cleaning process on a regular basis to confirm that the process is still under control. The time of this periodic revalidation should be specified in a cleaning validation policy (such as in the cleaning validation master plan), and typically is every one or two years. Such a periodic revalidation involves an evaluation of the monitoring data, change control, cleaning process deviations, and quality records of products manufactured after the cleaning process. If the monitoring data is adequate, the change control is minor, any deviations have had attributable to corrected causes, and there have been no product quality problems possibly related to cleaning, then all this information is suggestive of a cleaning process that is still under control. In such a case it is possible to document such findings in a revalidation report with a conclusion that the cleaning process is still under control and that the original validation work is still applicable. On the other hand, if the monitoring data show continual trends which require corrections, if numerous individual changes have been made (each of which was acceptable) but the overall cleaning process is now seen as significantly different, if deviations in the cleaning process have either not been attributable to a cause or the cause has not been corrected, and/or if there have been product quality issues related to the cleaning process, then such an investigation may result in a repeat of one or more PQ runs. In such a case, usually there will be some laboratory or pilot scale evaluations before PQ runs are performed.

ENZYME IMMUNOASSAY AND RELATED BIOANALYTICAL METHODS

John W.A. Findlay

Ira Das

St. Louis, Missouri, U.S.A.

INTRODUCTION

Enzyme immunoassay, a bioanalytical method incorporating an antigen–antibody reaction to capture the analyte of interest and an enzyme reporter system to detect the captured analyte, is one of the most widely used immunoassay formats. The method is sometimes applied only qualitatively to indicate the presence of an antigen in a matrix. However, in the more common quantitative implementation, a calibration (standard) curve is incorporated, from which the concentration of the analyte in unknown samples is interpolated. In the decades since the development of a radioimmunoassay for insulin by Yalow and Berson (1), immunoassays have been widely applied in support of medical practice and drug development. However, in recent years, there has been a decline in the application of immunoassays to the quantitation of low-molecular-weight xenobiotics, primarily due to the advent of liquid chromatography–mass spectrometry (LC–MS) methods, which have high sensitivity and specificity. This is particularly so for support of early drug discovery, where assay development times of as little as a day and analytical run times of only a few minutes per sample make LC–MS ideally suited to fast delivery of results to discovery scientists. Nonetheless, the remarkable specificity of antibodies allows their application in well-characterized immunoassays to the support of Phase III and Phase IV clinical trials as a cost-effective alternative to LC–MS methods. In addition, these methods are still widely used for therapeutic drug monitoring and analysis of low-molecular-weight hormones, such as steroids, in support of medical diagnostics. Immunoassays remain the method of choice for the quantitation of protein macromolecules and antibodies in complex matrices. Another major application of immunoassays is in the detection and quantitation of biomarkers, which are evolving to be of pivotal importance in the evaluation of pharmacological, toxicological, and clinical activities of candidate drugs (2).

Immunoassays generally vary in the type of critical antibody binding reagent or the detection and reporter systems used to monitor the end-point of the binding reaction. These different types of immunoassays have many characteristics in common; therefore, this chapter will include discussions of both enzyme immunoassays and other closely related methods. The enzyme immunoassay technique has been the subject of several textbooks, monographs, and review articles, including an excellent, comprehensive discussion in an earlier edition of this series (3). Thus, this chapter does not provide an in-depth review of the mechanistic details for producing and processing antibodies as reagents or on assay conditions for enzyme immunoassay. Rather, the intent is to present this technique in the context of several primary topics, namely the range of bioanalytical applications, the different, and sometimes additional, validation considerations imposed upon an enzyme immunoassay and its fraternal immunoassay methods, and some newer techniques that are complementary to enzyme immunoassay and offer potential performance enhancements. The chapter is written from the perspective of bioanalysis in biological fluids and does not address in any detail other applications of enzyme immunoassay, such as support of process control or product release, although such topics have been addressed elsewhere (4).

FORMAT OF ENZYME IMMUNOASSAYS

The format of an enzyme immunoassay refers to the configuration in which the components of the assay are assembled for routine application. Once this format has been established and assay conditions defined during assay development, they must remain unchanged through validation and subsequent application to sample analysis. Enzyme immunoassay formats fall broadly into two categories, namely heterogeneous and homogeneous. In a heterogeneous assay, at least one key reagent is

immobilized on a solid surface and there is at least one “washing” step before the final detection step. In contrast, in a homogeneous assay, all reagents are in solution together and there is no “washing” step prior to signal generation and detection. Both categories of assay include formats described as competitive and noncompetitive. In a competitive assay, there is direct competition between the labeled and the unlabeled antigen (analyte or ligand) in solution or, in some cases, between immobilized and soluble antigen for a limited number of antibody binding sites. In noncompetitive assays, antibody binding sites to capture and detect the antigen are not limiting because the antigen is incubated with excess capture antibody and enzyme-labeled detection antibody. An example of a competitive homogeneous assay format is the enzyme-multiplied immunoassay (EMIT) system (5), in which enzyme-labeled antigen competes directly in solution with unlabeled antigen in the biological sample (or calibration standard and quality control samples) for a limited number of antibody binding sites. The reaction endpoint is detected and quantitated spectrophotometrically without any intervening wash steps. This assay configuration is shown in Fig. 1. Enzyme-linked immunosorbent assay (ELISA) is an example of a heterogenous noncompetitive immunoassay. In this format, the primary antibody against the analyte of interest is immobilized on a solid plastic surface, usually a multiwell (or microtiter) plate. The biological sample is dispensed into the multiwell plate and incubated. The immobilized antibody then captures the analyte of interest, and the excess analyte is removed by washing. The antigen–antibody complex is then detected by two-step incubation with conjugated antibody and its substrate. First, an enzyme-labeled antibody, directed against the captured analyte, sandwiches the immobilized antibody–antigen complex. In a second incubation with an appropriate enzyme-specific substrate solution, a colored (or fluorescent or chemiluminescent) product is generated and quantitated spectrophotometrically. This assay format is depicted in Fig. 2. The ELISA can also be established in a competitive heterogenous format in which the antigen is immobilized on a multiwell plate and competition is established between the immobilized antigen and the antigen in solution for a limited number of binding sites on the primary antibody, also in solution. Following a fixed incubation period, the plates are washed and incubated with excess enzyme-labeled secondary antibody (directed against immunoglobulin from the species in which the primary, anti-antigen antibody was generated). The endpoint of this competition is then detected, following appropriate washing steps, by incubations with a signal-generating substrate. This assay format is depicted in Fig. 3.

It should be noted that the relationship between the final signal output and concentration of the analyte (dose–response) may be one of direct or inverse proportionality, and is dependent on the specific assay format. In addition, a number of different reporter enzymes may be used (e.g., horseradish peroxidase, alkaline phosphatase, β -galactosidase), along with a number of different signaling systems (e.g., substrates that yield chromogenic or fluorescent or chemiluminescent products, activation of signaling enzymes, amplification by biotin–avidin system or polymerase chain reaction).

ENZYME IMMUNOASSAYS FOR LOW-MOLECULAR-WEIGHT ANALYTES

Although the advent of sensitive LC–MS assays with short development times has reduced the need for immunoassays for low-molecular-weight compounds, the sensitivity, high-throughput and relatively low-cost characteristics of these assays still allow them to play an important role in some cases. Immunoassay support at the drug discovery stage may still be viable in such areas as the evaluation of biomarkers or determination of peptides, in which the elimination of sample cleanup prior to assay may constitute a valuable advantage of immunoassay over LC–MS. In addition, for low-molecular-weight therapeutic candidates, immunoassays can be used to support late-stage (Phases III and IV) clinical trials, when the metabolic pathways and the use of concomitant medications have been clearly defined. Critical to the application of immunoassay for analysis of low-molecular-weight compounds is the development of an antibody with clearly defined specificity for the analyte of interest. Low-molecular-weight compounds (less than 1000–2000 Da) are generally nonimmunogenic, or only weakly immunogenic, when administered directly to animals. To elicit an immune response producing antibodies suitable for use as reagents in immunoassays, these compounds must be conjugated to a carrier protein, e.g., bovine serum albumin (BSA), prior to immunization. This subject has been reviewed in depth previously (3). The immune system of the immunized animal responds to the carrier, and then secondarily to the hapten (the analog of the analyte bound to the carrier protein) attached to it. Although antibodies to the carrier protein are often produced in large amounts, they are easily removed by such techniques as affinity chromatography (6). Conversely, the desired antibodies to the analyte may be removed by affinity chromatography, which may also improve their specificity by eliminating or reducing

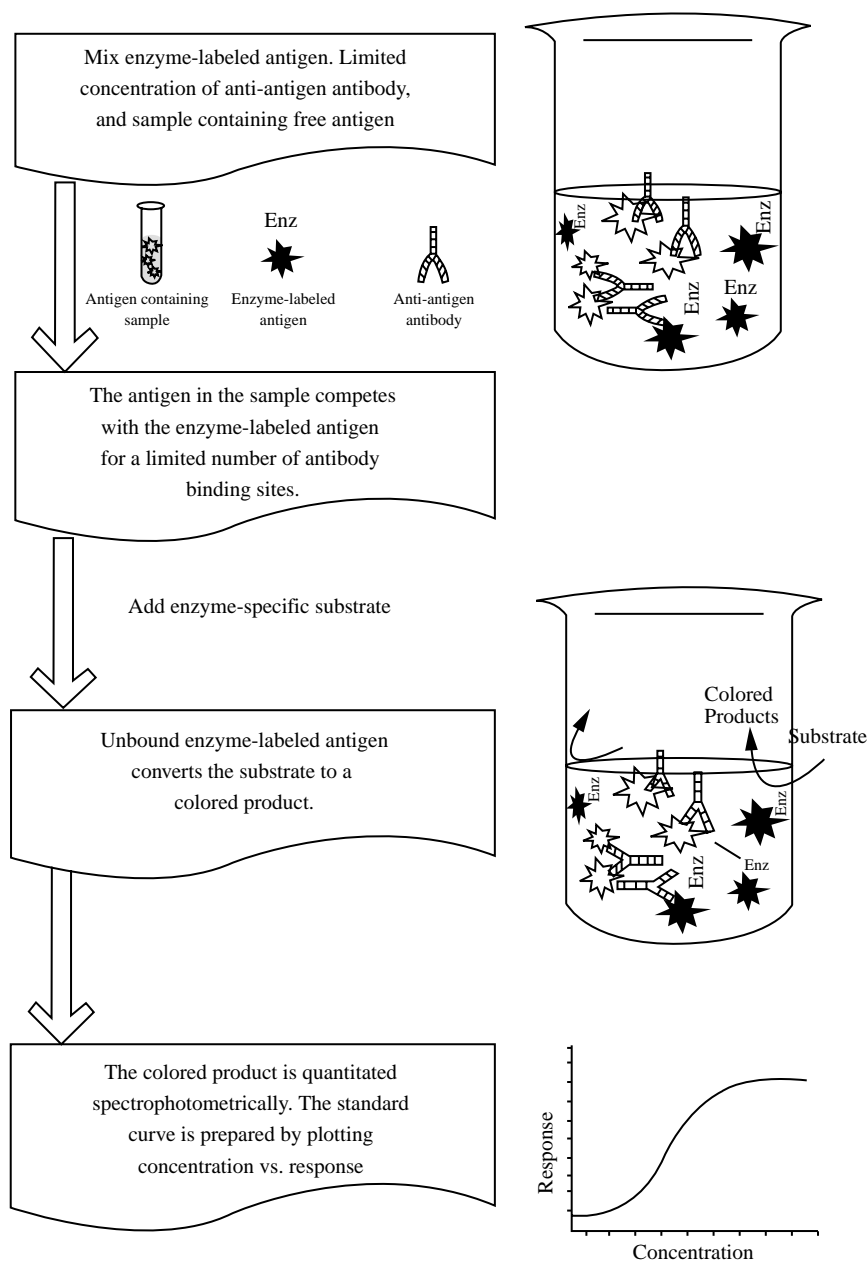

Fig. 1 An illustration of enzyme-multiplied immunoassay.

antibody populations that may cross-react with closely related chemicals, such as metabolites or degradation products. However, in many cases, carrier antibodies do not interfere in the assay to quantitate the analyte of interest and, therefore, anti-antigen antibodies in crude antiserum may be used in immunoassays without further purification. The site of attachment of the hapten to the carrier protein (either directly with the molecule via functional groups that are suitable for chemical coupling, or via a synthetic analog prepared to incorporate chemical

coupling functionality) will determine the specificity profile of the resulting antiserum. As a result, the site of attachment of hapten to carrier protein must be selected judiciously, considering all available knowledge of the metabolism of the compound in the animal system under investigation. Metabolic changes closest to the site of attachment will be poorly discriminated from the parent molecule, whereas metabolic changes distant from the conjugation site will be distinguished most clearly (i.e., will have lowest cross-reactivity). The ultimate

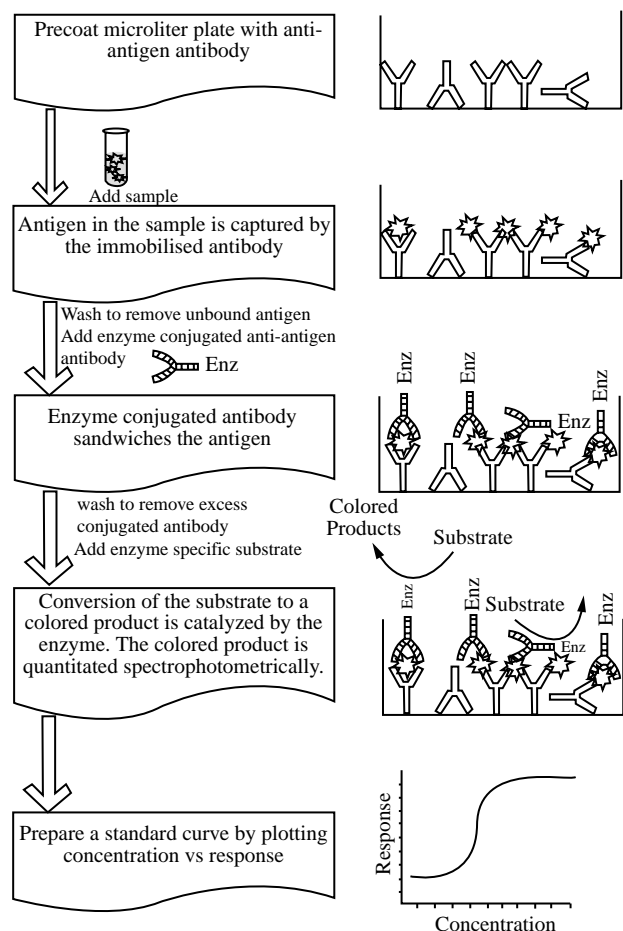

Fig. 2 An illustration of enzyme-linked immunosorbent assay.

result of this strategy is the ability of antibodies, and the resulting assays, to distinguish between enantiomers of chiral drugs (7). Although coupling methods generally have involved condensation reactions of hapten carboxylic or amino groups (or activated derivatives thereof) with amino or carboxylic groups on proteins, newer conjugation methods continue to be developed. These include the use of two-level, heterobifunctional agents such as *N*-(*m*-aminobenzoyloxy) succinimide, first to form a peptide bond to carrier protein and then, following diazotization of the aromatic amino group, to couple to a suitable hapten containing an imidazole, phenol, or indole residue. An example is the coupling of thyroid stimulating hormone to BSA (8). Another example involves interesting steroid chemistry in the preparation of an 11-Alpha-(3-Sulfanylpropyl)oxy hapten analog of the 3-Sulfamate ester of estradiol, and its subsequent coupling to bovine gamma globulin via a heterobifunctional crosslinker (9).

IMMUNOASSAYS FOR MACROMOLECULES

Immunoassays for macromolecules generally fall into one of two categories, namely those for endogenous proteins applied in support of clinical medicine (for example, assays for gonadotrophins or insulin) or those for new, genetically engineered proteins. The advent of genomics, proteomics, and recombinant technology has greatly advanced our understanding of the potential roles of regulatory proteins in the pathogenesis and modulation of diseases, and led to a sharp increase in the number of biological therapeutics under development. Several regulatory proteins are being developed as therapeutic agents and some have reached the market. Fig. 4 indicates the wide distribution of these agents across many different therapeutic categories, with a concentration in the field of cancer treatment. These products are often recombinant analogs of endogenous proteins, with the resulting challenge of developing enzyme immunoassays that are specific enough to distinguish between native and recombinant molecules.

Unlike low-molecular-weight xenobiotics, macromolecules are often immunogenic. An immune response is often elicited against several sites on the molecules called epitopes or antigenic determinants. The number of epitopes per antigen is determined by the size and complexity of the molecule. These epitopes can be linear, consisting of as few as four amino acids in a sequence, or conformational, involving different regions of the molecule in a three-dimensional configuration. Use of antibodies against conformational epitopes can be problematic if the antigen of interest loses its three-dimensional structure in vivo, or during sample analysis. In general, assay formats for macromolecules use at least two antibodies that react with two different regions of the molecule. Use of two antibodies against different regions of the molecule can confer additional specificity and may distinguish the analyte of interest from its metabolites or isoforms.

IMMUNOASSAYS FOR ANTIBODIES

Many of the new biological agents under development are recombinant versions of naturally occurring human proteins, or analogs of human proteins containing minor changes in their primary sequence, or differences in the extent of post-translation modifications. Marketed recombinant proteins include hormones (insulin, erythropoietin and growth hormone), enzymes (DNAase, asparaginase), cytokines (interleukins 1, 2, 11, interferon), growth factors

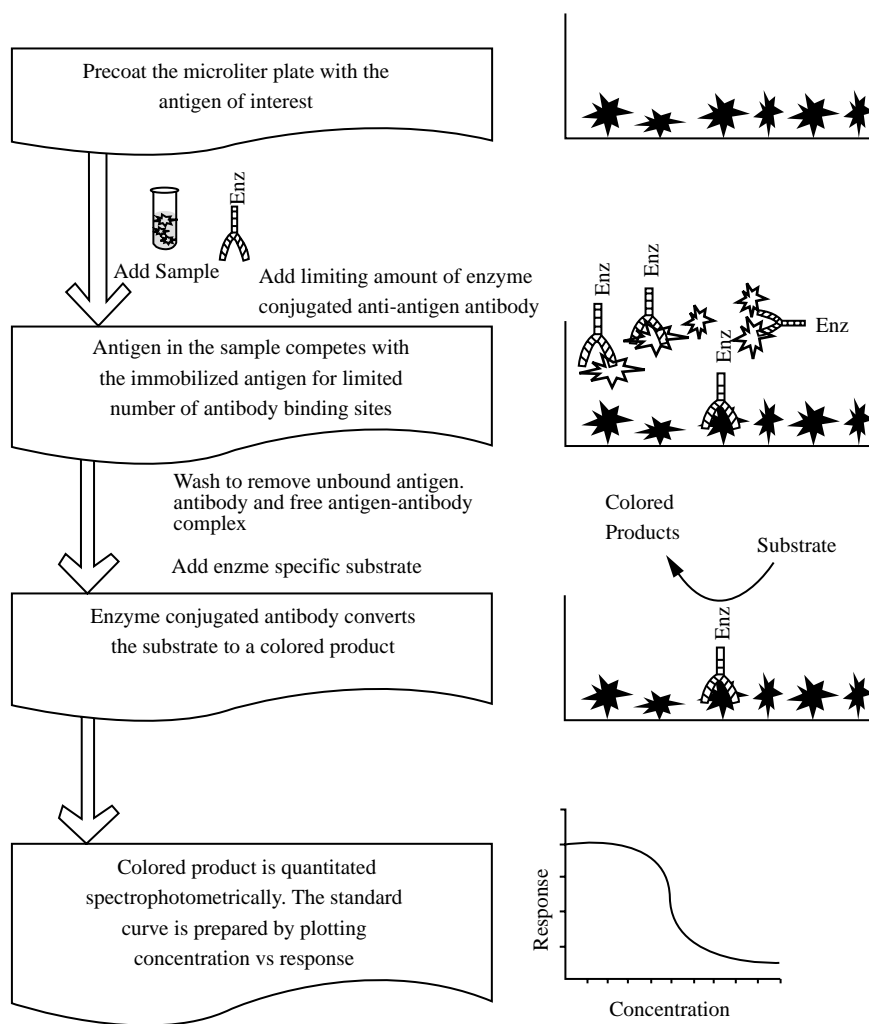

Fig. 3 An illustration of competitive enzyme-linked immunosorbent assay.

(G-CSF, GM-CSF), clotting factors (Factor VIII) and vaccines (hepatitis B). Some other biotechnology products are novel fusion proteins, such as etanercept (Enbrel[®]), whereas yet others are therapeutic antibodies, for example muromonab (Orthoclone OKT3), abciximab (ReoPro[®]), and trastuzumab (Herceptin[®]). Administration of these recombinant proteins to animals and humans may result in their recognition by the host's immune system as "non-self," resulting in an antibody response. Several factors contribute to the potential immunogenicity of these molecules, including the structure of the protein (including post-translation modifications), the presence of protein fragments or protein aggregates in the administered formulation, and the cell substrate or media components that may co-purify with the therapeutic agent. Clinical factors, such as genetic background, disease state or immune status, may also influence the immunogenicity of

a biological product, as well as the route and frequency of dose administration.

In both preclinical and clinical studies, evaluation of immune response to the administered product is necessary to evaluate accurately the safety, pharmacokinetic and pharmacodynamic response as anti-drug antibodies can bind the drug and neutralize the therapeutic effect, or eliminate it by Fc receptor-mediated uptake and destruction in the reticuloendothelial system. Conversely, the pharmacodynamic response could be enhanced if the distribution or clearance of the drug-antibody complex is altered (10). Antibodies to therapeutic agents may also react with the endogenous analog protein, abrogate its activity, and precipitate a severe adverse event. The presence of such antibodies may also interfere with the immunoassay for the quantitation of the therapeutic agent in biological matrices. In addition, the presence of

Fig. 4 Biotechnology products under development. (From New Medicines in Development, Biotechnology, PhRMA, April 1998.)

pre-existing antibodies (autoantibodies) to endogenous proteins can further complicate the quantitation of the molecule in biological fluids and its safety assessment in preclinical and clinical studies. Anti-drug antibodies may also interfere in imaging and diagnostic procedures utilizing antibodies; for example, human anti-mouse antibodies (HAMA) in the serum of patients treated with a murine antibody-based therapeutic may interfere in diagnostic assays using murine monoclonal antibodies.

Although several immunoassay formats [precipitin reactions, agglutination, radioimmunoassay (RIA), immunoradiometric assay (IRMA), western blot] have been used to detect and quantitate antibodies, enzyme immunoassay is the most commonly applied method. Several factors should be considered when developing an assay to detect the antibody response to a therapeutic agent. It is essential to understand the purpose for the antibody detection assay as it will influence the selection of the assay format. If the aim of the work is to detect only high-affinity antibodies with concomitant high specificity, a competitive assay format would be most appropriate. However, if all antibodies to the administered molecules (regardless of their affinity) are to be detected, best results will be obtained with a noncompetitive ELISA. In addition, random orientation of the antigen to expose all potential epitopes should be confirmed during assay development. These formats are illustrated in Figs. 5, 6. Product characteristics, such as the impurity profile, protein structure, and the presence of fragments and aggregates of the administered protein, need to be understood so that the most appropriate antigen is used in the assay. The potential loss of epitopes when the

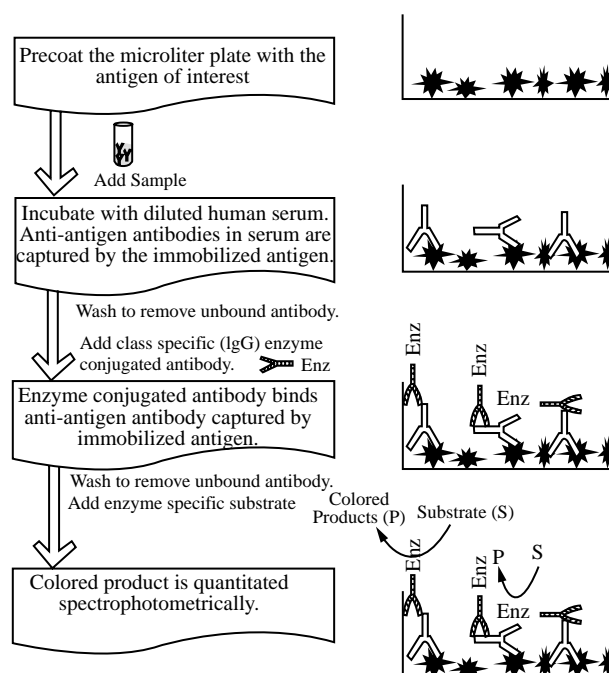

Fig. 5 An illustration of antigen capture antibody detection assay.

protein is directly adsorbed on the surface of the plate, the possibility of circulating antigen-antibody complexes, circulating antigen aggregates, and the source species of antibodies for capture and detection in the assay should also be evaluated. In some instances, cross-reactivity of the detected antibody with subclasses of the macromolecule (e.g., interferon) may need to be evaluated because the binding affinities of each subtype may vary greatly and may influence the interpretation of the results. Pre-existing antibodies can also limit the application of another antibody raised in the same species as that used in the assay configuration (e.g., as the detection antibody). Concomitant medications or high levels of the circulating macromolecular therapeutic agent may also be potential interferents in the assay.

Whether these assays should be established as truly quantitative is controversial. Although a quantitative response seems, from a bioanalytical perspective, desirable, the difficulties in so establishing the assay are significant and the added value is debatable. The primary challenge in developing a quantitative antibody assay is the lack of well-characterized, species-specific, polyclonal anti-drug antibody reference materials to be used as calibration standards (11). Heterologous polyclonal antibody could be used as reference standard (e.g., monkey antibody for human studies), or even nonspecific human IgG. However, although a true quantitative titer

Fig. 6 An illustration of antibody detection method using an antigen–antibody capture configuration.

value may be calculated with reference to a standard of one of these types, the greater value of ELISA assays for antibodies to macromolecules lies in comparative titers determined over time following administration of the candidate therapeutic protein, in conjunction with the assessment of any clinical sequelae.

IMMUNOASSAYS FOR BIOMARKERS

A biomarker is defined as an *in vivo* biological response to a disease or a toxicological event. Pharmacological markers are a subset of biomarkers that respond to drug intervention,

whereas surrogate markers are markers that predict clinical endpoints. In a clinical setting, biomarkers may indicate the response of a disease to therapeutic intervention. In the pharmaceutical industry, correctly chosen biomarkers may help with compound selection, identify mechanism of action, predict dose, demonstrate efficacy and, in cases where sufficiently sensitive assays are unavailable, substitute for direct pharmacokinetic evaluation. Identification of relevant biomarkers at the discovery stage will optimize target selection and validation, facilitate pre-clinical toxicological evaluation, and markedly shorten the time needed to demonstrate proof of concept in early clinical trials. Rapid and effective implementation of appropriate biomarker assays will result in major resource

savings in drug development. A biomarker may be a physiological measurement, such as blood pressure or heart rate, an enzyme activity, or a quantifiable discrete molecule. Biomarkers can be either low-molecular-weight analytes or large macromolecules. Many of these molecules (especially macromolecules) are measured by immunoassay, particularly by enzyme immunoassay.

Many biomarkers are found in blood and urine, where the basal levels may be low or high, depending on the nature of the marker. Thus, one of the additional challenges in establishing enzyme immunoassays for these analytes is obtaining analyte-free matrix for use in preparation of calibration standard and quality control samples. Appropriate analyte-free matrix may sometimes be prepared by extraction of the analyte from matrix by such techniques as affinity chromatography (6) or charcoal adsorption, but care must be taken to ensure that the processed matrix is still representative of the matrix to be analyzed. Alternative solutions to this problem include use of the same matrix type from a different species in which the endogenous biomarker does not occur, pooled baseline samples of low biomarker concentration, or use of a protein-containing buffer. In each case, dilutional linearity of study samples, containing high concentration of the analyte, with the assay matrix should be demonstrated. However, although calibration standards may be prepared in an alternative matrix, whenever possible the quality control samples should be prepared in the matrix to be analyzed so that they reflect the assay performance for the study samples. The concentration range for the calibration standards should attempt to bracket the anticipated concentrations of the biomarkers in both physiological (including such factors as circadian rhythm and intra-individual variability) and pathological states. The concentration levels in the quality controls should also reflect concentration levels in physiological and pathological disease states. Physiological levels may be affected by gender, race, intra-individual variation, circadian rhythm, and seasonal variations, whereas the levels in pathological samples may be affected by stage of the disease, intercurrent disease, current therapies, and overall patient status.

Another challenge in developing assays for biomarkers is the inconsistent availability of well-characterized reference standards. For many macromolecular biomarkers, purified species-specific reference materials are not available. If available, proteins are often not characterized by a standardized method. Different sources of antibodies may also give different results for the same lot of reference standard. It is suggested that crossover studies using standards, quality control pools, and some study samples should be conducted when the source or lot number of reference standard or antibody is changed.

The data from crossover studies will help to normalize study results obtained with different lots of reagents. In addition, biomarkers may exist in multiple forms, such as isoforms, or have homology with other biomarkers in the same class of molecules. Thus, an immunoassay may be developed to measure all forms nonspecifically or target a specific isoform. Cross-reactivity of the antibody selected for use in a biomarker assay should be rigorously tested for potential cross-reactivity with other isoforms and homologous molecules.

VALIDATION OF ENZYME IMMUNOASSAYS

Validation of bioanalytical methods has been a subject of increasing attention over the last 10–15 years. A conference addressing this issue, cosponsored by the US Food and Drug Administration (FDA), the Health Protection Branch (HPB) Canada, the American Association of Pharmaceutical Scientists (AAPS), the European Federation of Pharmaceutical Societies and the United States Pharmacopoeia (USP), was convened in Arlington, Virginia, in December 1990. The proceedings of this meeting, which came to be known as the Crystal City meeting, were published (12) and have subsequently been used as an informal guideline for bioanalytical method validation.

Since 1990, bioanalytical method validation has been a topic of discussion at the International Conference on Harmonization, and was also the topic of a draft guidance document from the FDA (13). Although, many of the validation considerations for chromatographic assays also apply to immunoassay validation, some of the unique considerations for immunoassays were not addressed in the draft guidance. The present authors, along with a number of pharmaceutical industry colleagues, have recently discussed validation issues specific to immunoassays (14). Topics covered in that review included the proper use of quality control (QC) samples for acceptance of assay runs, and statistical aspects of assay validation. Specifically addressed was the issue of how differences in bioanalytical techniques should be considered when developing validation acceptance criteria. In recent years, several publications have reviewed issues related to validation of immunoassays both broadly (15, 16), and specifically for assays for macromolecules (17). In 2000, two conferences were held to “revisit” the issue of bioanalytical methods validation in general (18), as well as specifically for assays for macromolecules, primarily immunoassays and cell-based assays (19).

As for any bioanalytical method, the extent of validation for an immunoassay should be related to the

intended application of the assay. Thus, if an immunoassay is intended to support rapid screening in discovery R&D, the characterization of specificity and the accuracy and precision specifications may be less stringent than if the assay is used to support preclinical and clinical development studies. Indeed, an assay for discovery support may be designed to detect active metabolites as well as parent molecule, so that an estimate of total, circulating, pharmacologically active agents may be made. However, at the development stage, such an assay may be applicable only with clear definition of the cross-reactivities of both the parent and the active metabolite in the assay.

DIFFERENTIATING CHARACTERISTICS OF IMMUNOASSAYS AND THEIR IMPACT ON VALIDATION

The key difference between chromatographic assays and immunoassays is the biological nature of the critical binding reagent in an immunoassay, namely the antibody. As antibodies are produced in biological systems, lot-to-lot variability may occur, and this is greatest for polyclonal antibodies because they are produced in whole animals. Monoclonal antibodies, produced from a single cell line in an *in vitro* biological system, tend to have much lower variability between different production batches. Immunoassays have at least one timed incubation period, which means that variations in binding affinity and avidity between different lots of antibody reagents can result in differences in rates at which equilibrium is reached. Another important difference between immunoassay and chromatographic assays is the use of analyte–protein and antibody–protein conjugates in immunoassays. During validation, the stability of these critical reagents should be demonstrated to ensure that their degradation does not adversely affect assay performance. The availability of reference standards may also differentiate chromatographic and immunoassay procedures. Thus, although well-characterized reference standards are readily available for low-molecular-weight xenobiotics, it is sometimes much more difficult to obtain similarly well characterized reference materials for macromolecule immunoassays. Macromolecular products are not always available in a highly purified state, and are often characterized in terms of biological activity rather than percentage purity. In some cases, more widely studied proteins are available as reference standards from independent agencies such as the World Health Organization.

Another important difference between immunoassays and most chromatographic assays, with significant implications for validation, is the nonlinear nature of the relationship between concentration and response for immunoassays. For optimum calibration curve fit, it is sometimes appropriate to include calibration points above and below the defined limits of quantitation. The calibration curve fit algorithm should evaluate the overall fit of the experimental data with and without the use of these additional standards in the asymptotic regions of the calibration curve. In general, the authors have observed that the use of additional standards in the asymptotic regions improves the accuracy and precision of the assay at the limits of quantitation. The option to include additional standards is not addressed in the draft FDA guideline for bioanalytical method validation (13), which states that the lowest and highest concentrations on the calibration curve should serve as the limits of quantitation.

Precision, accuracy and specificity also raise some interesting and different considerations for immunoassay methods. The biological nature of the reagents and the antibody–antigen reaction can potentially confer higher imprecision on immunoassays, and a larger number of validation runs may be needed to determine the true precision of the method. This higher imprecision also increases the likelihood that a higher number of assay runs will not meet the so called 4-6-20 rule relating to quality control acceptance criteria for method implementation (20, 21), leading to a recommendation (14, 19) that the 20% limit for accuracy be relaxed to 25% for immunoassays. However, as many immunoassays can also have precision comparable to that of chromatographic methods, the acceptance criteria should be determined based on the demonstrated capability of the method during validation and not set arbitrarily to 4-6-25 for all immunoassays.

Although antibodies can be exquisitely specific, the biological nature of these reagents also poses some new specificity issues for immunoassays when compared to chromatographic assays. In immunoassays, the analyte of interest is usually detected and quantitated directly (i.e., without prior extraction) in complex biological matrices such as serum, plasma, or urine. Furthermore, the specificity of the assay can potentially be compromised if cross-reacting metabolites of the analyte of interest are present in the study sample. Nonspecificity in immunoassays can arise from a variety of sources, but may be broadly classified as “specific” or “nonspecific” nonspecificity. Specific nonspecificity can arise from interferents that share similar physicochemical characteristics with the analyte of interest, and include metabolites, degraded forms of the analyte, impurities, or concomitant medications. For macromolecules, post-translation modified proteins,

protein aggregates or host anti-idiotypic antibodies may affect the specificity of the assay in a “specific” manner. Nonspecific nonspecificity arises from a variety of factors unrelated to the analyte, and is often referred to as “matrix effects.” Matrix effects may be due to hemolysis, lipemia, ionic strength differences, pH, serum proteins such as complement or rheumatoid factor, anticoagulants, binding proteins, autoantibodies or heterophilic anti-IgG antibodies. Nonspecific interferences may arise from the matrix chosen for preparation of calibration standards and quality control samples, or the study sample itself. Evaluation of the matrix should include comparison of the concentration–response relationship in spiked (and unspiked) matrix to that in a buffer matrix. Dilution with buffer may adequately decrease the intensity of matrix effects; however, if this approach fails, sample cleanup or full analyte extraction from the matrix may be needed. In these cases, it is important to treat all samples, including calibration standards, quality control or validation samples and study samples, identically, to obviate the need for recovery corrections in the assay.

VALIDATION CONSIDERATIONS FOR IMMUNOASSAYS FOR LOW-MOLECULAR-WEIGHT XENOBIOTICS AND MACROMOLECULES

An essential prerequisite component of small-molecule immunoassay validation is the demonstration of specificity for the analyte of interest. Assay interference (cross-reactivity) due to known metabolites, concomitant medications and, in some cases, endogenous molecules, should be evaluated. These experiments should assess the cross-reactivity of the potential interferents individually and in combination with each other and the analyte of interest to simulate the most likely biological milieu for the analyte. For small molecule immunoassays, the specificity of the assay should be established, whenever possible, by conducting a comparator study over a specified number of analytical runs, using a different, validated and specific bioanalytical method, such as LC–MS. Samples for these comparative analyses should be selected from an earlier study (incurred samples), and should have been collected at two or more time points following drug administration (e.g., approximate time of maximum plasma concentration and a succeeding time corresponding to several elimination half-lives) to allow performance of the immunoassay to be evaluated in an environment of increasing metabolite(s) concentration. If the immunoassay meets the predefined criteria for accuracy and precision

relative to the reference method, the immunoassay may be considered equivalent to the reference method.

The metabolism/catabolism of protein drugs and protein drug candidates is generally much less clearly elucidated than that of conventional small-molecule therapeutics. The dearth of information regarding the metabolism of protein-based drug candidates can hamper efforts to develop a highly specific and accurate enzyme immunoassay. In addition, there are few, sufficiently sensitive, comparator methods available to perform comparative analysis. Approaches to define specificity and, thus, predict reliability of a given assay, include epitope mapping experiments or the use of chromatographic separation prior to immunoassay, although the latter approach can be cumbersome and may result in markedly reduced assay sensitivity. Consequently, complete investigation of assay specificity for a therapeutic protein is more difficult than for a low-molecular-weight xenobiotic. The immunoreactivity of the analyte may be decreased with relatively minor changes in the region of antigenic determinants, such as a change in the amino acid sequence or by oxidation/deamination of an amino acid. On the other hand, proteolytic formation of major fragments of the parent protein may result in retention of the antigenic determinants and preserve the immunoreactivity of the protein metabolite. Such structural changes may or may not result in changes in biological activity, so that immunoreactivity may or may not correlate with biological activity in the study samples collected after administration of the protein. If assay sensitivity permits, methods such as chromatography or electrophoresis, coupled with immunoassay, may shed some light on the structural nature of the compounds in the study samples giving a positive response in the immunoassay. For many recombinant proteins, antigenic determinants of the therapeutic agent are often indistinguishable from those of the endogenous equivalent protein and, therefore, assays for such recombinant proteins are prone to interference from endogenous analog proteins. Such an occurrence poses challenges for the validation analyst in the selection of the preferred homologous matrix for the preparation of calibration standards, validation pools and quality control samples. The problem is accentuated when the administered doses of the exogenous product are so low that circulating concentrations are not increased markedly over the background endogenous concentrations. Clearly, in cases where in vivo concentrations of the exogenous product are very high after dosing, the contribution of low basal levels of the endogenous analyte to the total measured concentration may be small enough to be ignored. An alternative approach to this problem is to remove the endogenous analyte from the matrix by one of a number of methods, as discussed previously (under the heading

“Immunoassays for Biomarkers”) or to use a heterologous biological matrix devoid of the specific interfering endogenous substance for the preparation of calibration standards and control samples. In all of these approaches, it is important that the final prepared calibration curve reflects negligible bias due to the presence of endogenous analyte.

VALIDATION CHALLENGES FOR ENDOGENOUS ANALYTE AND BIOMARKER IMMUNOASSAYS

Immunoassays are often developed for the quantitation of endogenous equivalents of therapeutic molecules and biomarkers. Challenges in developing immunoassays for these compounds are similar to those experienced with macromolecules. As the biomarker is normally always present in the matrix of interest, it is difficult to obtain analyte-free matrices. Standard curves and lower limit of quantitation (LLOQ) validation pools may be prepared by choosing and pooling matrix from individuals with low baseline concentrations, diluting baseline samples with a protein-based buffer, or using an alternative species matrix with negligible concentrations of the analyte. The upper limit of quantitation (ULOQ) can be established by fortifying the baseline sample with the analyte of interest. Whenever possible, the appropriate biological matrix should be used for QC sample preparation. This may be a systemic matrix such as whole blood or plasma, or target-specific matrix such as sputum, cerebrospinal fluid, aqueous humor, platelets, T-cells or tissues. Alternatively, if no matrix effects can be demonstrated, quality control pools may be prepared in an “analyte-free” protein-based buffer.

As with macromolecules, obtaining well-characterized reference material can be difficult. Whenever possible, reference materials should also be species-specific. In situations where well-characterized standards are not available, crossover studies should be conducted to permit normalization of data obtained using reference standards from different vendors or different lots.

VALIDATION CONSIDERATIONS FOR IMMUNOASSAYS FOR ANTIBODIES

Anti-drug antibodies are polyclonal in nature and rarely does one have access to species-specific (especially human) anti-drug antibodies to prepare a calibration curve. Despite the problems associated with developing a quantitative anti-drug antibody assay, most validation parameters for immunoassays still apply. Although true accuracy cannot be determined, relative recovery using

quality control samples can be monitored through the life of the assays. Assay specificity evaluation should include assessment of any nonspecific binding of the antibody to the microtiter plate, potential interference of the administered protein, endogenous protein analogs, concomitantly administered drugs, and antigen–antibody complex or cross-reacting antibodies that may be present in the sample under evaluation.

A major issue with anti-drug antibody assays is definition and interpretation of a positive antibody response. During validation, a negative cut-off value, to distinguish antibody negative and positive results, should be determined by evaluating the analytical noise (imprecision) of the assay and the background absorbance readings from individual baseline samples from healthy volunteers and patients from the appropriate disease population. The recommended number of baseline samples is at least 25 (preferably 100) from each of the volunteer and patient groups. If the background responses tend to cluster closely together and the assay is precise, a negative cut-off can be defined as the mean absorbance ± 3 SD at a given dilution factor(s). If, however, there is greater variability in the background absorbance, developing a negative cut-off is more difficult. The cut-off should be based on an acceptable level of false negative and false positive results. The assay validation scheme should include a process to distinguish true responses from false positives. This is particularly important as auto-antibodies against various proteins may be present in otherwise healthy individuals. Several approaches can be taken to elucidate whether an apparent antibody response is truly positive, such as an alternative method for detecting the antibody (e.g., western blotting). In some cases, when antibody response is evaluated against several different antigens, true positives may be distinguished from false positives by cross-reactivity patterns. Finally, examination of the response prior to drug administration, and the change in this response over time, with continued exposure to the agent, will normally distinguish between true and false positives. In addition, results of *in vitro* neutralizing activity assays and clinical effects (*in vivo* neutralization) may provide further support for the presence of clinically significant, drug-specific antibodies.

MODERN TECHNOLOGICAL ADVANCES RELATED TO ENZYME IMMUNOASSAY

Immunoassays are inherently sensitive and specific. However, with continued need to develop increasingly sensitive assays to support preclinical and clinical

studies, there have been ongoing efforts to enhance the capabilities of these techniques. Advances in critical binding reagents, detection systems, new assay formats and automation have resulted in improved immunoassay technology.

Critical Binding Reagents

Although most immunoassays have used polyclonal antibodies as the critical binding reagents, development of monoclonal antibodies by Kohler and Milstein in 1975 (22), has resulted in their widespread use, particularly in assays for macromolecules. Their unique epitope specificity conveys advantages in double antibody immunoassays for proteins, where one monoclonal antibody may be used to capture the protein by a specific subunit or epitope, and another, directed against a different region or subunit of the protein, may be used to detect it. Use of antibodies against specific regions of the molecule can enhance the specificity of the assay such that one can distinguish the parent molecule from its catabolic products, one isoform from another, or an individual protein from its family members. Although monoclonal antibodies are highly specific, their affinity for the antigen is generally lower than that observed with polyclonal antibodies. Consequently, competitive immunoassays established with monoclonal antibodies as the critical binding reagent are generally less sensitive than those using polyclonal antibodies. For this reason, the application of monoclonal antibodies to competitive immunoassays for low-molecular-weight analytes has been limited.

A nonantibody binding reagent that has received increasing attention recently is the aptamer. Aptamers are oligonucleotide sequences that bind ligands or antigens in a way that is similar in many respects to antibody–ligand interactions (23). Thus, aptamers have been shown to bind with high affinity and selectivity to molecules as diverse as proteins and low-molecular-weight ligands. Aptamer libraries have also been generated, from which members with the desired binding properties may be identified and their concentrations enriched for use in binding assays. The use of these molecules as complements to, or substitutes for, antibodies has been reviewed elsewhere (24). These reagents offer the promise of similar sensitivity and specificity achievable with antibodies, without the need for time-consuming *in vivo* work to generate them.

Phage display technology provides a source of recombinant antibodies with defined affinity and specificity for use in immunoassay, without the need for extended immunization of animals. This approach

involves genetic manipulation of the coat proteins of the filamentous phage, a bacteriophage that lives on *Escherichia coli*. In one approach, the coding sequences of the antibody variable regions (Fv) are first isolated from spleen cells of immunized mice. The coding sequence for a single chain Fv fragment is then fused to the phage coat protein. With the assistance of a series of molecular biology steps, a library containing millions of single-chain antibodies can be displayed on the surface of the phage particles and released into the medium. Through a series of binding and elution steps (“panning”), the mixture of antibodies with the desired affinity and selectivity may be sequentially enriched. To obtain single-chain antibodies of suitable affinity and selectivity against new drug entities, one can repeatedly and rapidly screen the recombinant antibody phage library and avoid the traditional, time-consuming process of antibody production. A detailed discussion of antibody phage display technology is provided in reviews by Hoogenboom (25) or Peterson (26).

Molecularly imprinted polymers (MIPs) also offer some potential as synthetic alternative binding reagents (27) for assay of small molecules. These binding reagents are synthesized by polymerization of functional monomers (e.g., methylacrylic acid, 4-vinyl pyridines) in the presence of the ligand (antigen), which acts as a template. Depending on experimental conditions during polymerization, the template ligand may interact with the monomers by either noncovalent interactions, reversible covalent interactions, or metal-ion-mediated interactions, with the noncovalent approach being most commonly used. Upon completion of the polymerization reaction, the ligand may be washed out to leave its imprint in the polymer. The binding properties of these molecular imprints are characterized by remarkable specificity for the ligand originally imprinted. These MIPs have been applied in place of biologically derived antibodies for the binding assay of a range of low-molecular-weight analytes following extraction of the analyte from the biological matrix. The assays were initially conducted in an organic solvent. Under these conditions, a good correlation was found between the MIP binding assay and an established radioimmunoassay for theophylline (28). Subsequent developments of aqueous assay conditions led to a MIP-based assay for propranolol directly in plasma (29). These high-affinity binding reagents have high chemical and thermal stabilities, resulting in long shelf lives at ambient temperature, an advantage over antibodies. Additionally, although most MIP-based assays have employed radiolabeled analyte as the detection system, some recent studies have successfully used a fluorescence

detection system. However, there are currently some limitations with this technology. The MIPs often have lower binding affinities than do antibodies, resulting in lower assay sensitivities than immunoassays have. The use of MIPs is also limited to analytes stable in organic matrices, and further research is necessary to establish them fully in aqueous media, so that they are competitive with conventional immunoassays for the direct analysis of biological fluids.

Detection Systems

The need for greater sensitivity to monitor extremely low concentrations of either highly potent therapeutic agents, endogenous biomarker molecules, or environmental toxicants has been the primary driver in the development of newer detection systems as more sensitive alternatives to the chromogenic substrates normally used in enzyme immunoassay.

There are numerous examples in the literature of fluorescence being used in place of ultraviolet light absorption as the end-point detection system for an immunoassay. In particular, methods using time-resolved fluorescence detection (30) offer high sensitivity while largely avoiding the problem of background fluorescence in complex matrices by allowing this short-lived fluorescence to decay, before fluorescence of the labeled antibody complex is measured. These procedures frequently employ lanthanide chelates as the long-lived fluorophores. An interesting recent example of this method is the time-resolved fluoroimmunoassay for plasma enterolactone, a lignan produced from fiber-rich foods by intestinal bacteria, and thus claimed to be a biomarker of a healthy diet (31). This assay used a derivative of enterolactone coupled with a europium chelate as the fluorophore, and achieved sensitivity of 1.5 nmol/L. Examples from the pharmaceutical field include the assays for enalaprilat in human serum (32) and sampatrilat in human plasma (33), which are characterized by lower limits of quantitation of 200–500 pg/mL. In the technique of fluorescence polarization, detection is based on the change in polarization of light emitted by a fluorophore molecule when bound to an antibody. This change in polarization is correlated with the concentration of unlabeled antigen, and a standard curve is developed to interpolate the analyte concentration in an unknown sample. This method, which has the advantage of being homogeneous and easily automatable, has been widely available commercially for some time for such applications as therapeutic drug monitoring, but more recently has seen new application to high throughput screening in drug discovery (34).

Chemiluminescence (35) offers yet another sensitive detection system, which is easily implemented with simple instrumentation, but suffers to some extent from background interference in complex matrices. A recent example of an enzyme immunoassay with chemiluminescence as the detection system is the assay for 8-oxoguanine in DNA (36), which uses a secondary antibody conjugated with peroxidase–anti-peroxidase complex and a substrate solution containing hydrogen peroxide, luminol and *p*-Iodophenol.

The utility of chemiluminescence as a detection system has been extended greatly with the development of electrochemiluminescence. Although electrochemiluminescence has been studied since the 1960s, only relatively recently has the system been commercialized by the IGEN Corporation (Rockville, MD). In their system (37), a precursor molecule, tripropylamine (TPA) diffuses to an electrode surface to be activated, resulting in the excitation of a reporter molecule, ruthenium *tris*-bipyridyl. When the reporter molecule returns to ground state from the excited state, it emits a photon of light at a specific wavelength, which is detected by a sensitive photomultiplier tube. The system includes an electrochemical flow cell and magnetic bead technology to trap the ruthenium-tagged molecules on the electrode and thus allow the electrochemical cycle to proceed. Thus, in a typical immunoassay for a macromolecule, two different anti-analyte antibodies (recognizing different epitopes) may be used. One antibody may be labeled with biotin, which complexes with streptavidin-complexed magnetic beads, whereas the second antibody is labeled with the ruthenium complex. During incubation, the analyte is sandwiched between the two antibodies, after which the mixture is drawn into the flow cell, and the antigen–antibody complex is trapped on the electrode surface by magnetic forces. After washing, the amount of ruthenium complex in the trapped antigen–antibody complex is measured by activating the electrode and quantitating the emitted light. This method has been applied to bioanalysis of many analytes; an example is the biotin–avidin coupled assay for interferon alfa-2b in human serum, with a sensitivity of 4 IU/mL (38).

Detection systems have extended into the area of biosensors and immunosensors, with the application of surface plasmon resonance (SPR) in immunochemistry. SPR is one of a number of optical immunosensor techniques (39) in which a change in the resonance angle of incident light occurs when antigen–antibody binding takes place. In an instrument such as the Biacore, a typical experimental design might involve adsorption of an antibody to the gold or silver surface of a microcell, which is backed by a prism or diffraction grating. When a solution containing the antigen of interest flows through

the cell, the formation of the antigen–antibody complex results in a change in the angle of the reflected light (resonance angle) at the metal surface. The shift in the resonance angle has been reported to have a linear relationship to the concentration of antigen added to the system. As no labeled reagents are needed for this method, SPR can be quite simple; however, the technique cannot distinguish between antigen recognition and nonspecific binding, and poor sensitivity can also be a limiting factor. However, recent advances include the incorporation of liposomes linked to a sandwich immunoassay format, resulting in picomolar sensitivity in an assay for interferon (40). In another application for a low-molecular-weight xenobiotic, sulfamethazine, in milk, the analyte was covalently coupled to the gold surface of the sensor chip (41). The final response was the result of competition between covalently bound sulfamethazine and free antigen in calibration solutions and study samples for binding sites on polyclonal antibodies, also in solution. The assay sensitivity was in the range of 1.7–8.0 $\mu\text{g/kg}$.

Assay Configuration and Automation

When immunoassay specificity has not been inherent in the antibody employed in the assay, separation steps such as high performance liquid chromatography have been applied prior to immunoassay. One of the more promising of such coupled methods is capillary electrophoretic immunoassay (CEIA) (42). This method offers a number of potential advantages, including a smaller sample size and lower reagent consumption, simple and readily automatable process, potential for simultaneous determination of multiple analytes, and a broad range of detection techniques. When coupled with laser-induced fluorescence as the detection method and enzyme amplification, CEIA appears to be competitive with standard immunoassay techniques, with assay sensitivity in the 10-pM range. The resolving capabilities of CEIA can separate antibody-bound from free antigen, followed by application of the detection method. Thus, the technique is configured for on-line application. Although clearly having the potential for high throughput, CEIA has been applied only in a serial mode to date, analyzing one sample at a time. CEIA has been applied widely to the characterization of antibodies, as well as to immunoassay of a number of low-molecular-weight analytes, including digoxin, morphine and cortisol.

Immunoassay has achieved considerable success in the medical diagnostic arena largely due to its facile adaptation to automation, high sample throughput and relatively low per sample cost. Issues and challenges involved in the automation of immunoassays have been

addressed recently by Bock (43). An interesting recent application of enzyme immunoassay in an automated mode has been in the support of high throughput screening in drug discovery (44). In this case, the assay reagents are incorporated into a gel matrix rather than in a multiwell format, which permits 1,000–10,000 assays to be run per day, with the assistance of automation, by a single technician. The development of multianalyte immunoassays in miniaturized, microarray formats has also been reported (45).

The move toward automation has also led to development of online and flow injection immunoassays. These methods involve sequential injection of assay reagents and antigen–antibody reactions in flowing systems. One such system with some promise is flow injection renewable surface immunoassay (FIRSI), with fluorescence detection (46). In this flowing system, antibody-coated beads are retained on a flat surface adjacent to the detector; labeled and unlabeled analyte are then injected and flow over the beads, while reaction occurs. The beads are then washed, the final antibody-bound reading occurs at the detector and the flow is reversed to remove the beads in preparation for the next injection. Similar systems, sometimes using magnetic particle-coupled immunoglobulin to facilitate the separation of antibody-bound and free ligand (47), have been used in conjunction with electrochemiluminescence (48) or laser-induced fluorescence (49) as the detection methods.

CONCLUSIONS

Enzyme immunoassay is widely used, both in competitive and noncompetitive formats, for the bioanalysis of a broad range of low-molecular-weight compounds and macromolecules. Through the use of fluorogenic substrates and amplification systems such as avidin–biotin, the sensitivity of enzyme immunoassay has been developed to equal or exceed that of radioimmunoassay (50). The technique has found particularly wide applicability in the determination of new recombinant proteins, in demonstrating antibody responses to macromolecules, and in the measurement of biomarkers of disease, as well as in diagnostic medicine.

As for all bioanalytical methods applied to support of drug development, validation of immunoassays is important. However, several validation issues need special attention for immunoassays. These include stability of the critical reagents, the curvilinear nature of the calibration curve, the greater variability of immunoassays, and, particularly important, the specificity of the assay.

Finally, a number of newer binding reagents, detection methods, assay configurations, and automation applications are being investigated to develop further the potential of immunoassays. These include binding reagents requiring little or no animal immunization for their production, such as phage display antibody libraries, aptamer libraries, and synthetic molecular imprints. Detection methods such as electrochemiluminescence and surface plasmon resonance hold promise of sensitivity equal to, or better than, that of radioimmunoassay without the limitations of radioactivity. Progress has also been made in automation and miniaturization of immunoassays, as well as online techniques, such as CEIA and flow injection methods. These efforts will continue to ensure that improvements in sensitivity and specificity of immunoassays will be widely available through commercialization.

EXTRUSION AND EXTRUDERS

J.M. Newton

University of London, London, United Kingdom

INTRODUCTION

Extrusion is the process of forming a raw material into a product of uniform shape and density by forcing it through an orifice or die under controlled conditions. An extruder consists of two distinct parts: a delivery system which transports the material and sometimes imparts a degree of distributive mixing, and a die system which forms the material into the required shape. Extrusion may be broadly classified into molten systems under temperature control or semisolid viscous systems. In molten extrusion, heat is applied to the material in order to control its viscosity to enable it to flow through the die. Semisolid systems are multiphase concentrated dispersions containing a high proportion of solids mixed with a liquid phase. Extrusion is achieved by formulation to control the viscosity of the semisolid mass.

Extrusion is a continuous process that affords a consistent product at high throughput rates. The process has diverse applications in a range of industries utilizing extrusion equipment specifically designed or adapted to form a particular product. A description of the different types of extruders is given here, along with details that illustrate the versatility of extrusion processing.

THEORY AND CHARACTERIZATION OF EXTRUSION

The various types of extruders have the common feature of forcing the extrudate from a wide cross section through the restriction of the die. The force required and the characteristics of the extrudate produced are dependent on the rheological properties of the extrudate, the design of the die, and the rate at which the material is forced through the die. The theoretical approach to understanding the systems, therefore, is generally associated with dividing the process of flow into three sections: 1) entry into the die, 2) flow through the die, and 3) exit from the die.

Extrusion is dependent on the material, and the technique varies with the material studied. With regard to pharmaceuticals, most systems consist of particles dispersed in a fluid and, although consideration will be

given to plastics, the main emphasis is on paste extrusions. These differ in the fact that a fluid is present between solid particles. The relative position of solid and liquid can change during the various stages of the extrusion process, and hence produce effects different from those associated with single-phase systems.

If the die is considered as a simple capillary flow, the relationship between the rate of shear (γ) and die wall shear stress (τ_w) can be described by Eq. 1:

$$\tau_w = \gamma P \cdot R/2L \quad (1)$$

where P is the pressure drop across the length of capillary L and radius R . Corrections for entrance effects modify this equation by considering an increase in the length of the capillary to give Eq. 2:

$$\tau_w = \gamma P/2(L/R + n_b) \quad (2)$$

where n_b is the Bagley entrance correction (1). Determination of n_b can be made by measuring the pressure necessary to force extrudate through dies of different length-to-radius (L/R) ratio. Extrapolation of the graphs to zero pressure values gives the value of n_b as the intercept on the L/R axis (1).

Han and Charles (2) found experimentally that the exit pressure is actually above atmospheric pressure and proposed modification of Eq. 2 to Eq. 3 corrected for exit pressure losses:

$$\tau_w = (\gamma P - P_e)/2(L/R + n_b) \quad (3)$$

where P_e is the exit pressure. This value is difficult to determine and, because it is considerably lower than the pressure loss upstream and through the die, it is usually neglected. The upstream pressure loss can be considerable and can be determined as the intercept on the pressure axis at zero L/R ratio (the Bagley equation), giving Eqs. 4 and 5:

$$\tau_w = (P_T - P_0)R/2L \quad (4)$$

$$P_T = P_0 + 2\tau_w(L/R + n_b) \quad (5)$$

The upstream pressure loss includes pressure losses due to kinetic energy, head effects, elastic losses, and turbulence. Harrison (3) found for a series of pharmaceutical systems that the value of P_0 increases with increasing rate of passage through the die.

Rheological Curves

In addition to determination of the upstream pressure loss P_0 and the end correction n_b , Eq. 5 can be seen to provide a value for the shear stress τ_w in such systems. The slope of the graph P_T versus L/R has a gradient of $2\tau_w$; that is, the die-wall shear stress. The rate of shear at the die wall— $(dv/dr)_w$ —can be derived from the Hagen–Poiseuille's law, as in Eq. 6:

$$(dv/dr)_w = 4Q/R^3 \quad (6)$$

where Q is the volumetric flow rate and R the radius of the die. This assumes that the flow is Newtonian. If this is not the case, Jastrzebski (4) suggested that a correction should be made for the rate of shear, as in Eq. 7:

$$-(dv/dr)_w = \left(\frac{3n' + 1}{n'} \right) \frac{Q}{\pi R^3} \quad (7)$$

where n' is the degree of non-Newtonian flow; it is determined from the gradient of the graph of log-shear stress as a function of the log apparent shear rate. Wilkinson (5) has also indicated that these equations assume that: 1) the flow is laminar, 2) there is no slip at the die wall, and 3) the rate of shear depends only on the shear stress at the point of measurement and is independent of time.

Determination of shear rate versus shear stress curves by application of the ram extruder allow characterization of the rheological properties of the extruded material according to the basic type of curve, as expressed by Eqs. 8–11.

Newtonian:

$$\sigma_w = \gamma' \eta \quad (8)$$

where η is the apparent viscosity and γ' is the rate of shear.

Bingham body:

$$\tau_w = \sigma_y + \gamma' U \quad (9)$$

where σ_y is the stress necessary to be exceeded before Newtonian flow commences, yield value, and U is the plastic viscosity.

Power-law model:

$$\tau_w = K \gamma'^{n'} \quad (10)$$

where K is the power-law viscosity constant and n' is the degree of non-Newtonian flow. For values of n' less than 1, the material becomes less viscous with increasing shear rate (shear thinning), and for values of n' greater than 1, the viscosity increases with increasing shear rate (shear thickening).

Herschel–Buckley model:

$$\tau_w = \tau_y + K \gamma'^n \quad (11)$$

which allows for a system that has a yield value and a shear rate dependent on viscosity.

The application of these types of flow curves requires homogeneous materials that do not change in consistency with extrusion. Harrison et al. (6) found this not to be the case, and suggested that this was due to the presence of plug flow within the extrudate bulk and slip flow at the die wall.

The inability of the standard rheological models to quantitatively describe the process of flow into, through, and out of the die requires an alternative treatment. From a study of ceramic catalyst pastes, Benbow and Ovensten (7) and Benbow (8) assumed that there was broad plug flow at the center of the extrudate, with shearing occurring within a thin liquid layer at the die wall. Assuming that this layer behaves as a Newtonian liquid of thickness x and viscosity η , and that the initial shear stress to induce flow is τ_0 , the total die-wall shear stress τ_w at a given extrudate velocity V is given by Eq. 12:

$$\tau_w = \tau_0 + (\eta/x)V \quad (12)$$

The values of η and x cannot be determined directly and, therefore, Benbow et al. (9) introduced the term β , the die land viscosity factor, to replace η/x , as in Eq. 13:

$$\tau_w = \tau_0 = \beta V \quad (13)$$

Incorporation of this expression into Eq. 4 yields:

$$P_\tau = P_0 + 2(L/R)(\tau_0 + \beta V) \quad (14)$$

The value of τ_0 can be determined by plotting the extrusion pressure against the extrudate velocity V for extrusion through dies of constant value of L . The extrapolated value of extrusion pressure at $V = 0$ gives the value P_{0v0} at zero velocity, as shown by Eq. 15:

$$P_{\tau v0} = P_{0v0} + 2(L/R)\tau_0 \quad (15)$$

Thus, a graph of $P_{\tau v0}$ versus L/R provides the value of τ_0 as equal to half the slope. The value of β can be calculated by rearranging Eq. 14 to Eq. 16:

$$\beta = (P_{\tau_w} - P_{0w}) - (P_{\tau v0} - P_{0v0})2(L/R)V \quad (16)$$

where P_{τ_w} is the total extrusion pressure at extrudate velocity V , and P_{0w} is the upstream pressure loss at extrudate velocity V .

Further characterization of the system was suggested by Benbow (8) and Benbow and Bridgwater (10) in terms of a yield value σ_y associated with the convergence of flow

from the wide cross section of the feed to the narrow cross section of the die. This takes the form of Eq. 17:

$$P_0 = \sigma_y \ln(A_0/A) \quad (17)$$

where A_0 is the initial cross-sectional area and A that of the die. If the original and final cross sections are circular, Eq. 18 holds:

$$P_0 = 2\sigma_y \ln(D_0/D) \quad (18)$$

where D_0 and D are the barrel and die diameters, respectively. For materials that deform plastically and are time independent, the value of σ_y can be calculated from the intercept of the pressure axis divided by twice the natural log reduction ratio (D_0/D) for plots of P against L/R .

By combining this concept with those expressed above, Benbow et al. (9) and Benbow and Bridgwater (10) further modified the Bagley equation to Eq. 19:

$$P_T = 2(\sigma_{y0} + \alpha V) \ln(D_0/D) + 2(L/R)(\tau_0 + \beta V) \quad (19)$$

If the die land velocity factor β varies with the extrusion rate or the liquid layer at the die wall is non-Newtonian, Eq. 19 must be further modified to Eq. 20:

$$P_T = 2\sigma_y \ln(D_0/D) + 2(L/R)(\tau_0 + \beta^* V^{1-n}) \quad (20)$$

where β^* is a modified power-law constant and n the degree of non-Newtonian flow. If the flow velocity into the die is also dependent on the velocity of flow, Benbow et al. (9) and Benbow and Bridgwater (10) propose replacement of the yield value δ_y , by two empirical parameters, the initial die entry yield stress σ_{y0} and the die-entry yield-stress velocity factor α . Substituting in Eq. 18 gives Eq. 21:

$$P_0 = 2(\sigma_{y0} + \alpha V) \ln(D_0/D) \quad (21)$$

The fully corrected Bagley equation now becomes Eq. 22:

$$P_T = 2(\sigma_{y0} + \alpha V) \ln(D_0/D) + 2(L/R)(\tau_0 + \beta V) \quad (22)$$

The value of σ_{y0} can be obtained as the intercept from the derived zero-velocity graph of P_{0v0} as a function of L/R . The value of α , for a given system, is obtained from Eq. 23:

$$\alpha = (P_{0w} - P_{v0}) / (2 \ln(D_0/D)V) \quad (23)$$

where P_{0w} and P_{0v0} are obtained as described previously.

If the systems are treated as polymer melts instead of as paste (i.e., homogenous systems with no fluid migration during extrusion), further characterization of the wet masses can be achieved (11). The flow of melts through a capillary rheometer can be considered to show flow

streamlines converging and then accelerating, which according to Cogswell (12), is extensional flow. He separated the flow field into shear and tensile deformation and then described their calculation from the following equations:

$$TS = \frac{3}{8}(n+1)P_0 \quad (24)$$

where TS is the tensile stress (i.e., stretching), n is the power law index, and P_0 is the die-entrance press drop,

$$ESR = \frac{4\pi\gamma}{3(n+1)} = \frac{\gamma}{2} \tan \theta \quad (25)$$

where ESR is the tensile stretch rate, τ is the shear stress at the die wall, γ is the shear strain rate, and θ is the half angle of natural convergence.

$$EV \frac{TS}{ESR} \quad (26)$$

where EV is the apparent extensional (elongational) viscosity.

Such an approach depends on the flow fitting the power law model (i.e., Eq. 10), and that flow is not dominated by wall slip.

In addition to elongation flow, material can also exhibit elastic behavior. Two parameters that have been proposed (13, 14) to quantify this property are (1) recoverable shear RS and (2) compliance C . These can be derived from:

$$RS = \frac{P}{4\pi} \quad (27)$$

and

$$C = \frac{P}{4\tau^2} \quad (28)$$

Chohan (14) has used these to study the flow of branched polyethylene melt, and while what is exactly implied by these terms at high stretch rates is not clear, they are undoubtedly related to the elastic behavior of the material. The higher the values of each, the greater will be the elastic nature of the material.

MEASUREMENT OF RHEOLOGICAL PROPERTIES

The application of the theoretical treatment depends on the ability to measure the extrusion force and rate. Most commercial extruders do not allow for these types of measurement. Normal rheological equipment, such as cup-and-bob or cone-and-plate, do not have a suitable

geometry or instrumentation to handle materials of the consistency normally used. A ram extruder is a suitable experimental design.

The ram extruder, designed by Benbow and Ovenston (7), operates on a prefilled system and is used for experimental and small-scale extrusion (Fig. 1). It consists of a stainless steel barrel (2.54 cm internal diameter, approximately 20 cm in length), which acts as the material reservoir. The base is constructed to enable interchangeable dies, with central capillaries of varying dimensions to be bolted on. A rubber ring is inserted between the barrel and die to ensure a watertight connection. The piston, or ram, is a stainless steel rod that fits loosely into the barrel. A fluon ring positioned at its lower end provides a low-friction seal to prevent material escaping above the point where the piston moves down the barrel. The extrusion is a noncontinuous operation; first the material (50–100 g) is packed into the barrel and partially consolidated to a plug by inserting the piston. It is possible to add temperature control to the barrel to extrude materials that are thermosensitive. The barrel-and-die assembly is mounted on a rigid metal C-piece,

Fig. 1 Diagram of a ram extruder.

and a load is applied to the piston sufficient to extrude the material through the die. The ram extruder can be used in conjunction with an instrumented press. The piston is attached to the cross-head that may be driven down at various constant rates, and its displacement monitored by an attached displacement transducer. Output from this and the load cell is fed into an x - y chart recorder or computer. This arrangement enables the force acting on the material during extrusion to be recorded as a function of the displacement of the piston, and a force–displacement profile is produced.

A typical extrusion mixture produces three distinct regions, as shown in Fig. 2. In the compression stage, the piston descends into the barrel and consolidates the material into a plug prior to flow. This results in a large change in displacement accompanied by a small change in load. Eventually, the material is compressed to its minimum volume and maximum density. At this point, the pressure builds up while the material density is maintained. This is shown in the profile by a large increase in load accompanied by a minimal change in displacement. At the end of the compression stage, the pressure applied to the mass increases until it is high enough for the material to yield and commence flow. This is followed by a period of steady-state flow in which the force required to maintain the extrusion remains constant as the displacement increases. Forced flow occurs when steady-state flow can no longer be maintained. It leads to a gradual rise in extrusion force with displacement. This occurs often toward the end of the extrusion and is caused by the close proximity of the ram tip to the die face.

The force–displacement profile is altered by varying one of the extrusion parameters, such as the die diameter, L/R , or extrusion rate. For a given mixture, the relationship between the steady-state extrusion force, the die L/R at constant die diameter, and the extrusion rate can be represented graphically, as shown in Fig. 3. This is known as the Bagley plot (1). Used in this way, the extruder operates on a principle similar to that of a capillary rheometer, and expressions derived from capillary rheometry (described previously) may be used to characterize the properties of the wet powder mass. After conversion of the steady-state force values to pressure values, the slope of the relationship between the pressure and L/R is numerically equivalent to twice the value of the mean die-wall shear stress (according to Eq. 4). Plotting these values against the corresponding apparent die-wall shear rates (derived from Eq. 6) results in a flow curve that is unique for a particular wet-mass formulation (Fig. 4). The materials exhibit non-Newtonian flow and shear-thinning properties.

Fig. 2 Force-displacement profile for microcrystalline cellulose-lactose-water mixture.

PRACTICAL CHARACTERIZATION OF EXTRUSION SYSTEMS

The expression of the extrusion properties of pharmaceutical systems by numerical values could aid formulation. To be able to apply the theoretical approaches described previously, it is important to ensure that the restrictions of the systems are considered. One major problem with paste systems is that when subjected to pressure, there is phase separation resulting

in variations in the composition of the mass as it is being extruded. This can be detected by collecting the extrudate and measuring its water content (15, 16). Alternatively, magnetic resonance imaging has been used to quantify the water distribution within the barrel (17) and within the extrudate (18).

The extent to which die-wall slip is involved can be assessed by using dies of different lengths and diameters. An important characteristic that can be observed in the extrudate is its quality in terms of surface structure. Harrison et al. (19) have shown how this can vary from a smooth, regular surface via a rough, "shark-skinned" extrudate. There is obvious need to prevent this

Fig. 3 Steady-state extrusion force as a function of the length-to-radius ratio of the die for microcrystalline cellulose-lactose-water (5:5:6) at constant die diameter (1.5 mm) and extrusion rate (20 cm/min).

Fig. 4 Typical shear stress-shear rate flow curve for an extrusion mixture containing 50% microcrystalline cellulose extruded through a 1.5-mm diameter die.

phenomenon if extrudate of the correct quality is to be produced. The occurrence of the surface defects is associated with both the composition of the material and the operating conditions (e.g., die length and diameter and the rate of extrusion) (Fig. 5). Raines et al. (20) were able to relate the quality of the surface of the extrudate to the value of the yield stress at zero velocity δ_{y0} , in that those systems with a high value were smooth and regular while those with low values were shark-skinned.

Of the systems studied, most pastes show non-Newtonian behavior. This has important consequences for extruder design and operating conditions as material that are shear-rate dependent require careful handling. To date, most reported rheological investigations indicate that paste systems are shear thinning (i.e., their viscosity decreases with an increase in shear rate) (Fig. 4). Their extent of property can be quantified by obtaining the value of n' , the slope of the log shear-rate/log shear-stress graph. There is also some evidence that paste systems show plug flow (i.e., the central core of the extrudate moves at a constant velocity), while there is a thin layer of moisture at the die wall where shear takes place (21).

Fig. 5 A graph of ram force as a function of length-to-radius ratio, depicting conditions under which surface defects occur when extruding microcrystalline cellulose–lactose–water (5:5:6). Die diameter = 1.5 mm; ram speed cm/min: ■, 5; ●, 10; ▲, 20; ◆, 40.

FORMULATION

Extrusion mixtures are formulated to produce a cohesive plastic mass that remains homogeneous during extrusion. The mass must possess inherent fluidity, permitting flow during the process and self-lubricating properties as it passes through the die. The resultant extrudate must remain nonadhesive to itself and retain a degree of rigidity so that the shape imposed by the die is retained. Precise formulation requirements depend upon subsequent processing. Extrudate that is simply to be cut to short lengths to form cylindrical granules that are dried in a fluid-bed drier can be less rigid than extrudate intended for complex processing such as spheronization, where the extrudate undergoes a series of subtle shape changes.

The requirements for spheronization of the cylindrical extrudate are as follows:

1. The extrudate must possess sufficient mechanical strength when wet, yet it must be brittle enough to be broken down to short lengths in the spheronizer, but not to be so friable that it disintegrates completely. To achieve a narrow size distribution of spheres, the extrudate is ideally reduced to cylindrical rods of uniform length equal to approximately one and a half times their diameter (22).
2. The extrudate must be sufficiently plastic to enable the cylindrical rods to be rolled into spheres by the action of the friction plate in the spheronizer.
3. The extrudate must be nonadhesive to itself in order that each spherical granule remains discrete throughout the process.

A typical extrusion mixture might contain the following ingredients:

Drug	50–90%
Extrusion aid	
Microcrystalline cellulose, bentonite	5–90%
Binder	
Polyvinylpyrrolidone (PVP)	
Sodium carboxymethylcellulose (SCMC)	
Hydroxypropyl methylcellulose (HPMC)	
Fluid	
Water or solvent	

Extrusion offers the advantage of incorporating a relatively high proportion of active ingredient, up to 90%, in the final product. However, the physicochemical properties of the drug determine to a large extent the maximum quantity that can be included in a particular formulation. An extrusion aid is essential; microcrystalline cellulose is commonly used (23). The function of

microcrystalline cellulose is two-fold: it controls the movement of water through the wet powder mass during extrusion, and modifies the rheological properties of the other ingredients in the mixture, conferring a degree of plasticity which allows it to be readily extruded. This interaction with the liquid phase is both a physical and chemical phenomenon. The microscopic structure of microcrystalline cellulose is a random aggregation of filamentous microcrystals that create a high internal porosity and a large surface area, approximately 130–270 m²/g (24). This provides highly absorbent and moisture-retaining characteristics that are often unaffected by the extrusion process. This could be the essential quality that makes microcrystalline cellulose a unique material for extrusion. Bentonite and kaolin also have been used. Inclusion of 5–10% can significantly improve the extrusion properties of mixtures containing high proportions of drug. Recent work (25) has shown that it is possible to reduce the quantity of microcrystalline cellulose by adding glyceryl monostearate.

Additional ingredients may or may not be necessary. A binder increases plasticity and reduces extrudate friability, particularly when the content of microcrystalline cellulose is low. Natural or synthetic polymers, such as gelatin, PVP, or SCMC, may be incorporated into the mixture as a solid during dry mixing or in solution in the liquid phase. Commercial preparations of microcrystalline cellulose that are already combined with polymers are available. Examples include Avicel RC and Avicel CL grades of microcrystalline cellulose combined with SCMC (FMC Corporation). Variations in the type of microcrystalline cellulose significantly change the rheological properties of the mixture, and therefore, the extrusion characteristics (20). The differences between shear stress–shear rate flow curves of mixtures of microcrystalline cellulose–lactose–water (5:5:6) containing different particle sizes of microcrystalline cellulose and different quantities of SCMC are distinct but different. Inclusion of a polymer in the wet mass produces marked rheological differences. This has implications in the choice of formulations, since the extrudates formed from these various microcrystalline cellulose mixtures behave differently during subsequent processing, such as cutting, spheronization, and drying.

The mixture of dry ingredients is blended with water or a solvent such as ethanol (26) to form a dense cohesive mass suitable for extrusion. The liquid content of the wet powder mass and its distribution are highly critical and should be controlled so that they produce an extrudate that possesses the ideal characteristics. In general, these wet mixes have a much higher moisture content, typically 20–30 wt%, than is required for conventional (tablet)

granulations, the aim being to produce as dense a material as possible for passing through the extruder. Fluffy and incompletely wetted masses feed poorly and cause problems by creating excessive pressure and friction within the equipment. On spheronizing, they tend to produce large quantities of fines, and the “dry” extrudate is insufficiently plastic, forming dumbbell-shaped or ovoid pellets which never round off into spheres. On the other hand, if the mixture is too wet, it produces an extrudate that adheres to the spheronizer plate and to itself. This product tends to aggregate uncontrollably or at best produce spheres of wide-size distribution as the material is transferred from pellet to pellet via the plate motion.

The possible processability of different drugs by this approach has not yet been fully established. It is not possible to relate the pK_a , and freezing point depression, or to relate the ability to produce uniform pellets from a spheronization grade of microcrystalline cellulose (27). However, a relationship between the water solubility and the water level required by a formulation for equal parts of a series of model drugs and microcrystalline cellulose has been established (28).

INDUSTRIAL APPLICATIONS

Plastics

Extrusion technology is extensively applied in the plastics and rubber industries where it is one of the most important fabrication processes. Examples of products made from extruded polymers include pipes, hoses, insulated wires and cables, plastic and rubber sheeting, and polystyrene tiles. The most common extruder employed is the single-screw type (Fig. 6) with either cold or hot feed, which requires the polymer to be heated prior to processing. The extruder consists of a rotating screw inside a stationary cylindrical barrel. The barrel is often manufactured in sections that are bolted or clamped together. Usually, the inner surface of the barrel is grooved to reduce slippage and increase pumping capability. An end-plate die, connected to the end of the barrel, determines the configuration of the extruded product.

The extruder is conventionally divided into three sections: feed zone, transition zone, and metering zone. Resin granules are fed from a hopper directly into the feed section, which has deeper flights or flights of greater pitch. This geometry enables the feed material to fall easily into the screw for conveying along the barrel. The pellets are transported as a solid plug to the transition zone where they are mixed, compressed, melted, and

Fig. 6 Component parts of a single-screw extruder.

plasticized. Compression is developed by decreasing the thread pitch but maintaining a constant flight depth or by decreasing flight depth while maintaining a constant thread pitch (29). Both methods result in increased pressure as the material moves along the barrel. Most of the heat required to melt the material is supplied by the heat generated by friction as the resin granules are sheared between the rotating screw and the wall of the barrel. Additional heat may be supplied by electric heaters mounted on the barrel. The melt moves by circulation in a helical path by means of transverse flow, drag flow, pressure flow, and leakage: the latter two mechanisms reverse the flow of material along the barrel. The material reaches the metering zone in the form of a homogeneous plastic melt suitable for extrusion. For an extrudate of uniform thickness, flow must be consistent and without stagnant zones right up to the die entrance. The function of the metering zone is to reduce pulsating flow and ensure a uniform delivery rate through the die cavity. Some applications require a strainer plate fitted between the extruder and die plate to remove solid impurities or lumps of incompletely melted resin.

Polymers with a wide range of viscoelastic and melt viscosities cannot be processed with a single screw. Most

commercial extruders are, therefore, modular in design, providing a choice of screws or interchangeable sections that alter the configuration of the feed, transition, and metering zones. This makes it possible to modify the process to meet particular requirements, for example, from a standard to a high shear or high output extrusion. Modified screw designs allow the extruder to perform a mixing role in addition to extrusion, so that the material can be colored and blended. The various screw and die designs available and practical considerations of thermoplastic extrusion are reviewed by Whelan and Dunning (30). Extrusion processing requires close monitoring of the various parameters that affect polymer extrusion: viscosity, variation of viscosity with shear rate and temperature, elasticity, extensional flow, and slippage of the material over hot metal surfaces. Equations used to describe flow are included in the section on the "Theory and Characterization of Extrusion" presented earlier. Recent advances in the design and operation of extruders allow in-process monitoring and control of parameters, such as the temperature in the extruder, head, and die; pressures in extruder and die; wall thickness and other dimensions; "haul-off" speed and extrusion speed; and power consumption.

The process described above is known as profile or line extrusion in which the shape of the extrudate is determined by the die. The extruded profile proceeds horizontally to the cutoff equipment, which controls its length. It is then cooled to a solid state, usually by spraying with or immersion in water, and passed through a haul-off unit. Finally, it is cut to the required length or coiled. The downstream auxiliaries (e.g., such as haul-off equipment for handling the extrudate stream, collection machinery for winding or coiling continuous lengths of tubing or profiles, cropping and cooling equipment, and systems for monitoring the diameter and wall thicknesses of pipes on-line) are as important as the extruder itself (30, 31). Tubes and pipes and other solid cross-sections are mainly produced by profile extrusion. Profiles may be further processed, for example, as in film extrusion, blow molding, or injection molding (32).

Film extrusion

The polymer melt is extruded through a long slit die onto highly polished cooled rolls that form and wind the finished sheet. This is known as cast film. Plastic packaging film is also formed by blow extrusion, where tubular film is produced by extruding the melt, usually vertically, through an annular-shaped slit die. The extruded tube is inflated by air to form a large cylinder. The bubble is cooled externally by an airstream directed onto its surface and is collapsed on passing between a pair of rollers before being wound up. Film made by the casting process generally has better optical properties than blown film, but is less strong mechanically. Cast films usually require edge trimming at additional cost.

Blow molding

The plastic is heated to a melted or viscous state and a section of molten polymer tubing (parison) is extruded usually downward from the die head into an open mold. The mold is closed around the parison, sealing it at one end. Compressed air is blown into the open end of the tube, expanding the viscous plastic to the walls of the cavity, thus forming the desired shape of the container. The material cools in the cavity and solidifies. The mold is opened and the molding is removed. This technique is used for the manufacture of bottles, toys, and large containers.

Injection molding

The molten plastic is extruded into a cavity mold at high pressure. The material cools in the cavity and solidifies. The mold is then opened and the article is removed. Very intricate configurations can be obtained by this technique

(e.g., to provide intricate and strong components for the electronic, telecommunications, and clock-making industries).

Plastics that are commonly processed by extrusion include acrylics (polymethacrylates, polyacrylates) and copolymers of acrylonitrile; cellulose (cellulose acetate, propionate, and acetate butyrate); polyethylene (low and high density); polypropylene; polystyrene; vinyl plastics; polycarbonates; and nylons. The material properties and extrusion properties have been reviewed by Whelan and Dunning (30). Additives that may be included to modify or enhance properties (33) include lubricants and antislip agents to assist processing during extrusion; plasticizers to achieve softness and flexibility; stabilizers and antioxidants to retard or prevent degradation; and dyes and pigments.

Food

In principle, any food that can be formed into a paste can be processed by an extruder. Food extrusion has been utilized since the 1930s for pasta production. Modern equipment and processing techniques allow the manufacture of complex products in a variety of shapes and sizes. Raw materials such as cereals, oil seed, and protein, along with carbohydrates and water mixtures, can be converted into products such as meat substitutes, pet foods, and snack meals. A widely used and versatile technique combines cooking and extrusion in a so-called extrusion cooker (34). It has the potential to manufacture a range of novelty or specialty products, such as breakfast cereals (expanded and shaped cereals), shaped and filled snacks, protein-fortified and precooked pasta products, and precooked meat pieces for convenience foods. The process is highly economical, and provides mixing, high temperature–short duration cooking, texturizing, and shaping of the food in one step. The equipment closely resembles the screw extruders used in the processing of thermoplastics. The screw is designed to create varying zones along the barrel, allowing the food substance to be processed in stages. The solid and liquid starting materials are fed from a hopper to the feed zone of the extruder and conveyed to the transition zone. Here the materials may be compressed, mixed, sheared, and heated to form a viscous plastic dough. In the metering zone, the plastic mass is subjected to further heating and shearing before being pumped into the die to form the shaped product. The pressure drop on leaving the die causes superheated water to flash off the molten material. If the dough contains starch, gelatinization will result in an expanded porous product with a crunchy texture (35). Finally, the product may be cut, shaped by passing through rollers, dried, and packed.

The viscosity of the dough may vary more than an order of magnitude during the extrusion cooking process as a result of changes in shear rate, temperature, moisture content, and induced physicochemical changes such as protein denaturation, polysaccharide gel formation, and reorientation of molecules (36). For this reason, success in food extrusion requires accurate monitoring and control of feed rate, screw speed, temperature, and moisture to produce and control desired product characteristics. Knowledge of the viscous rheology of the food mixture in the metering section immediately prior to extrusion is of particular importance. However, this is not easily predicted since, unlike the case of homogeneous or simple mixtures of polymers where the major change is melting, food doughs are of such complexity that the exact chemical composition and structure cannot readily be determined. Efforts have been made to develop semiempirical models derived from plastics extrusion to describe the apparent viscosity of cooking doughs, which may be useful in evaluating food formulations (37, 38). Remsen and Clarke (36) used an Instron capillary viscometer and amylograph to describe the relationship between the viscosity of a typical soy flour dough and the applied shear rate, temperature, and time-temperature history. Fletcher et al. (39) investigated the viscous dough rheology of maize mixtures as a function of the extrusion variables (pressure, shear, and temperature). They used an instrumented single-screw extruder fitted with slit dies, and related the results to the product properties. The advantage with this method is that the food material receives a deformation history corresponding to the extrusion cooking process, which is otherwise difficult to replicate in a laboratory rheometer.

Animal Feed Production

In the animal feed industry, extrusion is applied as a means of producing pelletized feeds, commonly in the form of short cylindrical rods of 4–8 mm in diameter. Pellets are a convenient means of precisely controlling the animal's diet. They offer several advantages (40). The quantity of feed the animal receives is better controlled by pellets than a loose-mix feed, and a complex diet of controlled composition is easily produced. The pellet feed can contain as many as 30 single ingredients mixed in the correct proportions. The animal is obliged to chew pellet feed with improved palatability and therefore, digestion. During extrusion, the feed mixture is compressed, resulting in a densified product that requires less storage space.

Pellets are prepared from a mixture of raw materials of varying chemical composition (starch, oil, fiber, and

moisture) and physical characteristics (particle size, bulk density, and moisture-retention properties). The composition of a typical poultry feed is often complex (41). The raw material properties determine the quality of pellet formation. Equipment performance and pellet quality (friability, size uniformity) can be improved by a small amount of extrusion or pelleting aid (binders, lubricants) (42). Additives commonly used in the feed industry include molasses with binding properties when activated by steam; fatty acid lubricants to reduce product-metal friction when extruding or pressing through long dies; lignosulfates (organic materials derived from lignin in trees that improve pellet quality and throughput rates); and mineral binders, such as ball clay and bentonite, or cellulose binders, such as sodium carboxymethylcellulose. It should be noted that in small quantities cellulose binders can improve the pelleting process and reduce pellet friability.

The pelleting process (40) consists of blending and conditioning the feed mixture immediately prior to pressing, pressing itself, cutting of the pellets, and cooling. The complexity of the feed mixture, composed of a number of ingredients of different particle sizes and densities in varying proportions, requires thorough blending to ensure homogeneity. The product is conditioned by adding moisture, typically up to 15%, and heating to a controlled temperature in order to gelatinize the starch or convert it to simple sugars. This reaction causes the starch to act as a binder and converts the meal into a physical state suitable for pressing. The most efficient means of conditioning and heating is by steam. Optimal conditioning parameters, moisture content of the material, temperature, and duration of heating depend on the composition of the mixture (42). For example, high starch-low fiber meals require temperatures of 80–85°C, whereas feeds that contain heat-sensitive ingredients, such as milk and sugar, have a temperature limit of 55°C (39).

Extrusion Pressing

According to Sebestyen (40), pellet mills may be classified into disk-die presses or ring-die pellet mills. In the former, the die consists of a circular plate resting in the horizontal plane into which holes are drilled in a regular pattern. A set of rollers move around the upper surface of the disk, sweeping the meal in their path through the holes and compressing it to form pellets or cubes. Rotating adjustable knives located beneath the disk cut the extrudate to an appropriate length. In another design, the plate revolves while the rollers and knives remain fixed.

Ring-type pellet mills have a radially arranged die resting in the horizontal plane with rollers rotating and revolving along the inner surface. The rolls are offset from the die face, leaving a slight clearance that allows buildup of a thin product layer, optimizing throughput efficiency. The peripheral velocity of the rollers depends upon the die diameter; that is, higher speeds are required for smaller-diameter holes and lower speeds for larger-diameter holes.

Cooling

On leaving the extruder, the warm pellets are pliable and prone to abrasion and deformation. Therefore, a final processing stage is required to harden the pellets (40). Cooling equipment placed directly beneath the mill employs ambient or chilled air to reduce the temperature and remove excess moisture from the final product.

PHARMACEUTICAL INDUSTRY

Extrusion processes are applied within the pharmaceutical industry to produce a variety of dosage forms such as suppositories, implants, and granulations.

The large-scale manufacture of suppositories and pessaries uses either the fusion method where the drug is dispersed in a molten base and the mixture poured into molds to solidify, or the cold compression method (43, 44). In the latter process, the medicament and cold-grated base, usually theobroma oil or witepsol base, are intimately mixed and placed in a cylinder. The mass is extruded by means of a piston through small holes that connect with the mold. The cavities are filled by pressure with the mass which is prevented from escaping by movable end plates. The plates are removed and the suppositories ejected by further extrusion. The extrusion equipment is chilled to prevent melting of the

Fig. 7 Schematic of extrusion processing in the pharmaceutical industry.

components due to the heat generated by the friction of compression.

The most important application of extrusion in the pharmaceutical industry is in the preparation of granules or pellets of uniform size, shape, and density that contain one or more drugs. The process involves a preliminary stage in which dry powders, drug, and excipients are mixed by conventional blenders, followed by addition of a liquid phase and further mixing to ensure homogeneous distribution (Fig. 7). The wet powder mass is extruded through cylindrical dies or perforated screens with circular holes, typically 0.5–2.0 mm in diameter, to form cylindrical extrudates. These may be further processed, for example, by cutting and drying to yield granules, or by spheronization (24) to yield spherical granules followed by drying. The spheroids are usually coated with a polymer to control the rate of drug release and filled into hard gelatin capsules to yield a multiple-unit dosage form.

Extruders Used for Pharmaceuticals

Commercial extruders may be classified according to the die design and the feed mechanism that transports the material to the die region.

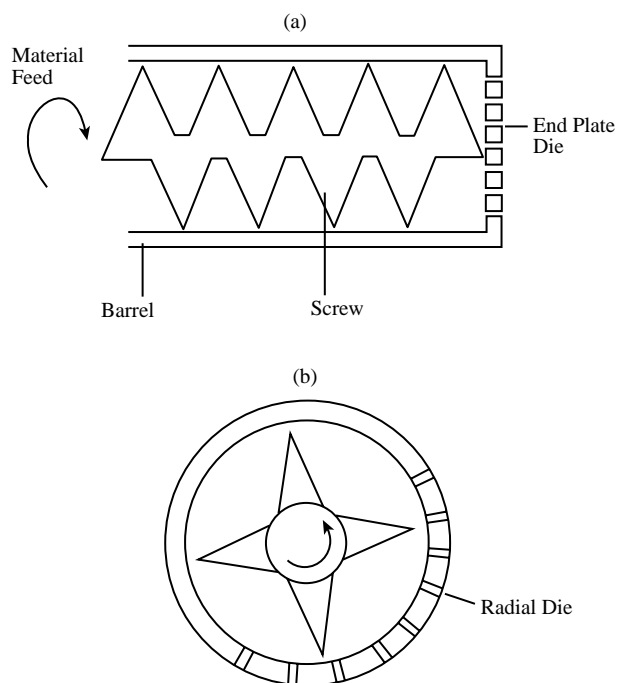

Fig. 8 Screw extruder with (a) end-plate die and (b) radial-screen die.

Fig. 9 Twin-screw extruder with radial-screen die. (Manufactured by Fuji Paudal Company, Japan.)

Screen extruders

Screen extruders utilize a screw-feed mechanism consisting of single or twin helical screws rotating in a barrel to convey the damp mass from a feed hopper to the die zone. The die consists of a thin steel plate perforated with numerous holes, which is positioned radially or axially to the screw feed (Fig. 8). The advantages of this arrangement are high continuous throughput rates, from 5 kg/h of wet mass for a laboratory-scale single-screw extruder, up to 800 kg/h for a larger twin-screw design. The screens are easily cleaned and interchanged; they have holes of varying diameter beginning at 0.5 mm and are available commercially. The disadvantage of this type of equipment, however, is that the screw mechanism can exert a high pressure on the material, generating excessive friction and heat as the wet mass passes between the screw and barrel. This is particularly the case with axially orientated dies. These extruders tend to have a high dead volume that contains stagnant material between the feed screws and the screen. Consideration should be given to this if the wet powder mass contains ingredients that are unstable when wetted with water. The low L/R of the die holes can also result in low compaction in the extrudate and distortion of the surface finish, known as shark-skinning. This problem can sometimes be overcome by varying the throughput rate, which will be discussed later.

The twin-screw design and radial-die screen assembly of an extruder manufactured by the Fuji Paudal Company of Japan is shown in Fig. 9. Water can be circulated

Fig. 11 The rotary-cylinder-type extruder.

through the hollow extrusion rotors to maintain a constant temperature in the extrusion zone. This is a useful facility when processing heat-sensitive materials and for controlling temperature, extrudate moisture levels, and viscosity. Interchangeable screens are available with die holes ranging from 0.5 to 1.5 mm in diameter, allowing the production of a wide range of extrudates. Explosion-proof motors, with fixed or variable speed drive, are fitted for safe processing of wet masses granulated with inflammable solvents. All components in contact with process materials are constructed of high-grade stainless steel. An additional feature is the option of fitting an axial die plate in cases where a denser extrudate is required.

A screen extruder that operates with a novel mechanism is the Nica System Extruder (Fig. 10), manufactured in Sweden. It consists of a radial screen encircling an extrusion rotor and a rotating disk fitted with angled impeller blades or baffles. Above this is a counterrotating central feed blade. Speeds of both the extrusion rotor and the feed blade are variable. Material, such as gravity fed from a hopper, is swept into the blades and pressed through the holes in the screen. According to the manufacturer, there are several advantages to this equipment. First, pressure is exerted on only a small quantity of mass and only at the point of extrusion; that is, just between the baffles and the screen. Second, temperature increase is minimal, and a moisture gradient between the wet mass and extrudate is avoided. Because of this, cooling facilities are not necessary. The dead volume, located in front of each baffle, is limited and may be as low as 15 g per baffle. A small extruder with output up to 4 kg/min is available for development and small-scale production.

For larger production, an extruder with output of up to 12 kg/min is available.

Rotary-cylinder extruder

The working principle of this machine is based on two counterrotating cylinders (Fig. 11). The granulating cylinder is perforated and acts as the die. The diameter and the L/R of the holes can be varied. The holes are spaced further apart and are drilled rather than of punched sheet construction as in the screen-type extruders. The other cylinder is solid and acts as a pressure cylinder. Material is gravity fed from a hopper to the die region between the cylinders and adheres to the knurled surface of the solid cylinder, building up a thin layer that is pressed through the die cylinder. Although the extrusion is a continuous process, actual material flow through each hole is intermittent due to the rotation of the die. Pressure is built up in the perforations, which compacts the wet mass and forces the extrudate to the interior of the cylinder. This pressure is dependent upon the diameter and the length of the perforations. Hence, with die holes of high L/R , this system can achieve good densification of the wet powder mass. This is important in giving the most granules mechanical strength and stability for further processing. Another advantage is the lack of a dead zone, which is limited to the thin layer of material adhering to the pressure cylinder. Since the cylinders only apply pressure to a small quantity of material in the feed zone, there is little tendency for creating moisture gradients. However, cleaning of the granulating cylinder can be troublesome. The material remaining in the die holes can be difficult to dislodge, particularly when the L/R is high. Furthermore, the granulating cylinders are expensive because of the high costs of drilling stainless steel.

A cylinder extruder manufactured by Alexanderwerk (Germany) is shown in Fig. 12. With this equipment, the feed stock material can be metered to the working area. On the smallest machines this is accomplished by a rotary-table feed hopper. On larger machines, the feed rate is controlled by screw feeders sited through the feed hopper. The throughput rate depends on the diameter and L/R of the die holes, as well as on the feed rate. Laboratory-scale extruders with a throughput range of 30 to 50 kg/h use granulation cylinders 70 mm in diameter. Production-scale equipment with a larger granulating cylinder (186 mm diameter) can achieve an output of 100–105 kg/h. Interchangeable cylinders with die holes of 1.0–5.0 mm are available. A multiple-unit assembly consisting of three parallel

Fig. 12 The cylinder extruder, manufactured by Alexanderwerk, Germany. (a) Laboratory-scale extruder. (b) Die cylinder and pressure cylinder.

extrusion heads can achieve even higher throughput rates of up to 3000 kg/h.

When scaling up production, the die cylinder dimensions cannot be increased proportionately, since the wall thickness and therefore, die L/R become too high. This results in excessive extrusion forces imparted on the material. This is overcome by using special counter-bored die cylinders with reduced depth perforations to provide optimal extrusion conditions at scale-up. The temperature increase in the extrudate is minimized by circulating cool water through the pressure cylinders. A scraper blade attachment inside the perforated cylinder cuts off the extrudate to shorter lengths, making it more manageable.

Rotary-gear extruder

The rotary-gear extruder operates on a similar concept to that of the cylinder extruder. It consists of two hollow counterrotating gear cylinders with counterbored dies, described by the manufacturer (Bepex, Berwind Corporation) as nozzles, that are drilled into the cylinders between the teeth (Fig. 13). The material, gravity fed from a hopper, is drawn in by the toothed cylinders and pushed through the nozzles into the center of the cylinders, where scrapers cut off the extrudate. The product is compacted as it passes through the nozzles, and thereby forms a dense extrudate. The density depends on the nozzle L/D (the ratio of nozzle length to nozzle diameter). Higher throughput rates can be attained with this type of extruder, since output is achieved through both rotating-gear wheels. The equipment and the gear-toothed cylinders are shown in Fig. 13b.

Interchangeable gear cylinders are available with variable nozzle L/D ratios by counterboring from the inside of the rollers to reduce the die length or by using replaceable nozzle inserts to increase the die length. The diameter of the holes can be varied from 1.0 to 10.0 mm to produce a range of pellet sizes. The throughput rate can be controlled by varying the cylinders' rotation speed and the corresponding feed rate. Throughput capacity ranges from 20 kg/h for the small-scale laboratory extruders to approximately 1000 kg/h for production equipment. For large equipment or materials with poor flow characteristics, agitators can be installed in the hopper to prevent bridging; special hoppers with conical feed screws fitted with additional wipers are used for highly viscous products. The machine can be furnished with cooling equipment, circulating water through the compaction gears for processing materials that need temperature control. An alternative pharmaceutical gear extruder, similar in design to the above, has recently been marketed by G.B. Caleva Ltd., United Kingdom.

Fig. 13 (a) Rotary-gear extruder. (b) Gear-toothed cylinders.

Ram extruder

Industrial ram extruders are commonly used in the plastics and rubber industries for the preparation of warm strip feed for large cold-fed screw extruders and for forming strips or slugs for feeding injection molding and compression molding machines. They are used in the extrusion of specialized substances that require critical in-process control or that are not readily amenable to processing by screw extruders. Examples include the extrusion of waxlike substances such as coloring crayons,

dental waxes, and rocket propellant, and in the extrusion of moist powders and claylike materials, such as blackboard chalks. Ram extrusion allows control of parameters, such as temperature, size, and weight of extrudate. An example of a high performance ram extruder, as manufactured by Borwell International Ltd., United Kingdom, is shown in Fig. 14. It consists of a chrome-plated barrel positioned in a thermostatically controlled storage tunnel. A range of dies can be fitted to the extruder head. Material is loaded into the barrel by manual or mechanical means and vacuum is applied to eliminate air from the system. The material is extruded by means of an hydraulically powered ram, with the hydraulic (oil) fluid being passed through a special valve system to sense changes in the plasticity of the material and compensate ram pressure to achieve an even extrusion through the hole. A multispeed cutter mounted on a fly wheel severs the extrudate at the die face. The volume of the extrudate is a function of the cut speed and the set ram speed, and can be controlled to a high degree of accuracy within $\pm 1\%$. A continuous operation is possible with the help of a twin barrel and ram arrangement in which material is fed to each barrel in turn by a screw system. Various sizes of extruder are available, from 4.5-L barrel capacity up to 80 L, offering production rates up to a maximum of 800 kg/h.

Choice of extruder

The selection of the extruder design is based on the principal requirements of the extrudate and the nature of further processing. For the production of uniform granules to be dried in a fluid-bed drier, a low-compaction system, such as that provided by the various types of screen extruders may be suitable. Cylinder or gear-type extruders may be more appropriate when aiming for a densified extrudate, such as that required for spheronization. Ram-extrusion systems, which allow precision control of extrudate density, size, and shape, are ideal for the extrusion and forming of pharmaceutical polymers of the type used for subdermal implants.

Consideration should be given to the availability of small-scale equipment, which is vital for development work prior to scale-up on pilot- or production-scale machines. Equipment choice is not necessarily based on maximum throughput rate, since the subsequent processing stages (e.g., cutting, spheronization, and drying) are batch processes and are therefore, a rate-limiting factor in production. Since extrusion is a continuous process, it allows adequate production rates for most purposes with any of the above mentioned extruder types.

The equipment must comply with the code of Good Manufacturing Practice (GMP) standards within the

Fig. 14 The Barwell ram extruder.

pharmaceutical industry. Machines should be constructed of durable material with smooth surfaces to discourage adhesion of extraneous material and facilitate cleaning. Materials used for equipment construction must not affect the product. They should be corrosion resistant and able to withstand cleaning disinfectants. All surfaces and parts in contact with the product must therefore be of high-grade stainless steel and designed to exclude contamination of process material or product by lubricant during manufacture. Controls should be accessible by means of recessed contact buttons.

NOMENCLATURE

A_0	initial cross-sectional area	n_b	Bagely entrance correction
A	die cross-sectional area	P	pressure drop along die
C	compliance	P_e	die exit pressure
D	die diameter	P_0	upstream pressure loss
D_0	barrel diameter	P_{0w}	pressure drop at zero velocity
$(dv/dr)_w$	rate of shear at the die wall	P_T	total pressure drop
ESR	tensile stretch rate	P_{t_v}	pressure drop at velocity v
EV	apparent elongational viscosity	Q	volumetric flow rate of extrudate
K	power law viscosity constant	R	radius of capillary (die)
L	length of capillary (die)	RS	recoverable shear
n	degree of non-Newtonian flow (power law index)	T	tensile stress
		U	plastic viscosity
		V	extrudate velocity
		x	thickness of Newton liquid layer
		α	die entry yield stress velocity factor
		β	die and velocity factor
		γ	rate of shear
		η	apparent viscosity
		σ_y	yield value
		σ_{y0}	yield value at zero velocity
		θ	half angle of convergence
		τ	shear stress
		τ_0	die wall shear stress at zero velocity
		τ_w	die wall shear stress
		τ_y	shear stress to be exceeded before flow commences

EXPIRATION DATING

Leslie C. Hawley

Mark D. VanArendonk

Pharmacia Corporation, Kalamazoo, Michigan, U.S.A.

INTRODUCTION

Expiration dating of pharmaceuticals corresponds to the determination of a retest period for drug substances and an expiration dating period or shelf-life for drug products. The shelf-life, or expiration dating period, of a drug product is defined as the time interval that a drug product is expected to remain within an approved shelf-life specification, provided that it is stored according to label storage conditions and that it is in the original container closure system. The Expiry/Expiration Date is the actual date placed on the container/labels of a drug product designating the time during which a batch of the drug product is expected to remain within the approved shelf-life specification if stored under defined conditions and after which it must not be used. To arrive at an expiration date, it must be determined first for how long and under what conditions a pharmaceutical formulation can meet all of its quality specifications. In general, this issue is answered through stability testing that monitors chemical and physical product attributes as a function of time, temperature, and other environmental factors. It is not the intent of this article to discuss the mechanics of starting a testing program or to provide an exhaustive discussion of all the testing requirements necessary to establish an expiration dating period. Rather, this discussion focuses on changes in worldwide regulatory requirements pertaining to expiration dating since the last edition of this publication (1), the statistical treatment of stability data to determine a shelf-life for a given drug product, the impact of postapproval changes on the expiration date of a drug product, and finally, a discussion of unresolved issues in expiration dating.

REGULATORY CONSIDERATIONS

Before 1990 there was no official harmonization of stability testing requirements for countries throughout the world. In the United States, the major reference documents outlining regulations or guidelines pertaining

to expiration dating at that time were the Code of Federal Regulations (CFR) (2), the *United States Pharmacopeia* (USP) (3), and the 1987 FDA Guideline for Submitting Documentation for the Stability of Human Drug and Biologics (4). In Europe there was the European Community Guide to Good Manufacturing Practices for Medicinal Products (5), which contained minimal information pertaining to expiration dating. More extensive European guidelines at that time were found in the Note for Guidance, Stability Tests on Active Substances and Finished Products (6). In Japan, the primary reference for the determination of expiration intervals for the approval of a drug product was given in a guideline entitled, at that time, Draft Policy to Handle Stability Data Required in Applying for Approval to Manufacture (Import) Drugs (7) and Draft Guidelines on Methods to Perform Stability Test (8). Very little information pertaining to expiration dating was available for Zone III/IV countries. There were many similarities among the requirements for each of the regions of the world, but there were also many differences. Because the stability testing requirements for many countries and also the regulations pertaining to expiration dating periods were different, a systematic approach to establishing stability protocols adequate for worldwide registration and harmonization of expiration dates in the different regions of the world was virtually impossible.

Since 1990, significant gains in the harmonization of technical requirements for registration of pharmaceuticals for human use were achieved with the inception of the International Conference on Harmonization (ICH). The ICH convened for the first time in 1990, and the first draft of the ICH Tripartite Guideline on Stability Testing of New Drug Substances and Products was issued on March 23, 1992. In that Guideline, the stability testing requirements for the United States, European Union, and Japan are defined. Approved ICH guidances include (9):

- Q1A Stability Testing of New Drug Substances and Products
- Q1B Photostability Testing of New Drug Substances and Products

Q1C Stability Testing for New Dosage Forms

Q5C Stability Testing of Biotechnological Biological Products

Additional DRAFT ICH guidances currently in the early review stages are:

Q1D Reduced Designs for Stability Testing of Medicinal Products

Q1E Statistical Analysis and Data Evaluation

In addition, both European and U.S. regulators have published regional guidances that complement or supplement the ICH guidances regarding the stability requirements for establishing the expiration dating of pharmaceutical products. Harmonization of stability testing requirements for Climate Zone III/IV countries has also begun (10). Below, the stability testing requirements and regulations pertaining to expiration dating are broken down by major geographical regions.

United States

The current U.S. requirements pertaining to expiration dating and the stability testing necessary to establish expiration dates of pharmaceutical products are covered in the USP (11), The Code of Federal Regulations, the ICH guidances mentioned previously, and the Draft FDA Guidance for the Industry (12). The three relevant sections of the CFR cover: 1) where expiration dates must appear on a product (§201.17); 2) what products are required or exempted from having an expiration date (§211.137); and 3) requirements for stability tests and the testing program (§211.166). Because the pertinent sections of the CFR for human pharmaceuticals are brief, they are presented later in this article. The USP covers the same general information as the CFR. The FDA Draft Guidance for the Industry titled, Stability Testing of Drug Substances and Drug Products (12) has replaced the original guidance entitled, Guideline for Submitting Documentation for the Stability of Human Drugs and Biologics, published in February 1987. The guidance is intended to be a comprehensive document that provides information on all aspects of stability data generation and use. It references and incorporates substantial text from ICH Q1A, Q1C, Q1B, and Q5C. The guidance provides recommendations regarding the design, conduct, and use of stability studies necessary to establish expiration dates and to support various regulatory applications.

§201.17 DRUGS: LOCATION OF EXPIRATION DATE

When an expiration date of a drug is required, e.g., expiration dating of drug products required by §211.137 (see the next section) of this article, it shall appear on the immediate container and also the outer package, if any, unless it is easily legible through such outer package. However, when single-dose containers are packed in individual cartons, the expiration date may properly appear on the individual carton instead of on the immediate product container (43 FR 45076, Sept. 29, 1978).

§211.137 EXPIRATION DATING

1. To assure that a drug product meets applicable standards of identity, strength, quality, and purity at the time of use, it shall bear an expiration date determined by appropriate stability testing described in §211.166.
2. Expiration dates shall be related to any storage conditions stated on the labeling, as determined by stability studies described in §211.166.
3. If the drug product is to be reconstituted at the time of dispensing, its labeling shall bear expiration information for both the reconstituted and unreconstituted drug products.
4. Expiration dates shall appear on labeling in accordance with the requirements of §201.17 of this article.
5. Homeopathic drug products shall be exempt from the requirements of this section.
6. Allergenic extracts that are labeled "No U.S. Standard of Potency" are exempt from the requirements of this section.
7. New drug products for investigational use are exempt from the requirements of this section, provided they meet appropriate standards or specifications as demonstrated by stability studies during their use in clinical investigations. When new drug products for investigational use are to be reconstituted at the time of dispensing, their labeling shall bear expiration information for the reconstituted drug product.
8. Pending consideration of a proposed exemption, published in the Federal Register, September 29, 1978, the requirements in this section shall not be enforced for human over the counter (OTC) drug products if their labeling does not bear dosage limitations and if they are stable for at least 3 years as supported by appropriate stability data (43 FR 45077,

Sept. 29, 1978, as amended at 46 FR 56412, Nov. 17, 1981; 60 FR 4091, Jan. 20, 1995).

§211.166 STABILITY TESTING

1. There shall be a written testing program designed to assess the stability characteristics of drug products. The results of such stability testing shall be used in determining appropriate storage conditions and expiration dates. The written program shall be followed and shall include:
 - Sample size and test intervals based on statistical criteria for each attribute examined to assure valid estimates of stability
 - Storage conditions for samples retained for testing
 - Reliable, meaningful, and specific test methods
 - Testing of the drug product in the same container-closure system as that in which the drug product is marketed
 - Testing of drug products for reconstitution at the time of dispensing (as directed in the labeling), as well as after they are reconstituted.
2. An adequate number of batches of each drug product shall be tested to determine an appropriate expiration date and a record of such data shall be maintained. Accelerated studies, combined with basic stability information on the components, drug products, and container-closure system, may be used to support tentative expiration dates, provided full shelf-life studies are not available and are being conducted. Where data from accelerated studies are used to project a tentative expiration date that is beyond a date supported by actual shelf-life studies, there must be stability studies conducted, including drug product testing at appropriate intervals, until the tentative expiration date is verified or the appropriate expiration date determined.
3. For homeopathic drug-products, the requirements of this section are as follows:
 - There shall be a written assessment of stability, based at least on testing or examination of the drug product for compatibility of the ingredients and based on marketing experience with the drug product to indicate that there is no degradation of the product for the normal or expected period of use.
 - Evaluation of stability shall be based on the same container-closure system in which the drug-product is being marketed.

4. Allergenic extracts that are labeled “No U.S. Standard of Potency” are exempt from the requirements of this section (43 FR 45077, Sept. 29, 1978, as amended at 46 FR 56412, Nov. 17, 1981).

EUROPEAN UNION

In addition to the ICH, the Committee for Proprietary Medicinal Products, under the European Agency for the Evaluation of Medicinal Products (EMA) (13), issued, in 1997 and 1998, a number of stability-related guidances to be used for establishing stability testing protocols for drug products to be filed in European countries. The documents complement and supplement the ICH guidelines and are listed below:

1. Reduced Stability Testing Plan-Bracketing and Matrixing: Annex to Note for Guidance on Stability Testing of New Drug Substances and Products (14)—CPMP/QWP/157/96
2. Note for Guidance on Maximum Shelf-Life for Sterile Products for Human Use After First Opening or Following Reconstitution (16)—CPMP/QWP/159/96
3. Note for Guidance on Declaration of Storage Conditions for Medicinal Products in the Products Particulars (17)—CPMP/QWP/609/96
4. Note for Guidance on Stability Testing of Existing Active Substances and Related Finished Products (18)—CPMP/QWP/556/96
5. Note for Guidance on Stability Testing for Type II Variation to a Marketing Authorization (19)—CPMP/QWP/576/96
6. Note for Guidance for In-Use Stability Testing of Human Medicinal Products—Annex to Note for Guidance on Stability Testing of Existing Active Substances and Related Finished Products and Note for Guidance on Stability Testing of Existing Active Substances and Related Finished Products—CPMP/QWP/2934/99

Japan

In addition to ICH guidelines, the specific Japanese stability testing requirements for establishing expiration dating are described in the regional guidelines. In particular, the Japanese Ministry of Health and Welfare (MHW) has issued a guidance entitled, *Handling of Data on Stability Testing Attached to Applications for Approval to Manufacture or Import Drugs* (22). For the

most part, the MHW guidance complements the ICH guidelines. The MHW guidance provides more detailed requirements for “stress” testing than that found in the ICH and the guidances for stability testing used in United States or European Union (see above). In fact, specific stress testing conditions and testing duration and frequency are provided. In contrast, European Union and the U.S. regional guidances do not recommend specific testing conditions and schedules and specify that stress testing is usually accomplished during routine formulation and analytical methods development. This discrepancy between the regional requirements in Japan versus those in European Union and the United States is a notable opportunity for harmonization.

Climate Zone III/IV Countries

Currently countries in climate Zones III and IV are not member countries of the ICH, although it has been recommended by Grimm (14) that the ICH Tripartite Guideline be extended to include Zone III/IV countries. Needless to say, great strides in the harmonization of stability testing requirements and expiration dating for climate Zone III and IV countries has begun. The definitive source on stability testing requirements can be found in a set of guidelines published by the World Health Organization, entitled, *Guidelines for Stability Testing of Pharmaceutical Products Containing Well-Established Drug Substances in Conventional Dosage Forms* (15). This document outlines the conditions and testing required for Zone III and IV countries. Also contained in that document are a list of recommended storage conditions to be prominently indicated on the label of pharmaceutical products distributed in climate Zone III and IV countries. Another set of guidelines relevant to stability testing in climate Zone III and IV is a document issued by MERCOSUL (“Mercado Comunal del Sur” or “Common Market of the South”), entitled *Pharmaceutical Products Stability* (10). The MERCOSUL document was specifically intended for use as a guidance for designing stability testing programs by countries that are members of MERCOSUL, Argentina, Paraguay, Uruguay, and Brazil. The stability testing requirements described in the MERCOSUL guidelines essentially match the conditions and testing requirements in the WHO document. The stability testing requirements for Zone III and IV, for which the WHO guidelines are considered the definitive requirements, are just now being implemented throughout the industry to support marketing of pharmaceutical products in climate Zone III and IV countries.

STATISTICAL DETERMINATION OF SHELF-LIFE FROM LONG-TERM STORAGE DATA

The current approach to analyzing stability data to predict shelf-life involves statistical analysis of long-term storage data. The accelerated data are generally used as supportive data. In particular, it is recommended in ICH Q1A, CPMP QWP/556/96, and the FDA Draft Guidance that a shelf-life of a drug product be determined by the point at which the 95% one-sided confidence limit for the mean degradation curve intersects the acceptable lower specification limit. Typically, statistical analysis to determine shelf-life is applied to at least 12 months of long-term storage data on three production scale batches of drug product. Data from individual batches are first treated by least-squares fitting. The true line representing degradation behavior is not known a priori, but it is estimated by least-squares analysis. The confidence interval about the least-squares line from fitting the stability data is also obtained. As noted above, it is the intercept between the line representing the confidence limit and the upper or lower registration limit that yields the expiration period. If the application of appropriate statistical tests to the slopes and zero time intercepts of the regression lines for the individual batches indicate that the batch-to-batch variability is small (e.g., p values for level of significance of rejection of more than 0.25), and therefore, the data pool, it is advantageous to then combine all the data into one overall estimate for shelf-life. If it is inappropriate to combine data from several batches, the overall expiration dating period is determined by the minimum time a batch may be expected to remain within acceptable and justified limits (9, 12). Detailed information about the statistical evaluation of long-term stability data using regression analysis, tests for batch similarity, and data pooling is described in Carstensen (16), Wessels (17), Lin (18), Bancroft (19), and the FDA guidance (12).

Software packages that handle the statistical evaluation of stability data per the ICH or FDA guidelines are sold commercially. Also, the FDA has developed and makes available its own drug formulation stability test program, STAB, which can be downloaded from the FDA website (20). This statistical approach to calculating the expiry dating period from long-term data applies to new drug substances and their products (9, 12) as well as products containing established unstable substances (15).

Often the expiration dating period determined by the statistical analysis described above results in extrapolation

of the regression lines to times for which there are no stability data available. For extrapolation beyond the observed range to be valid, the assumed degradation relationship must continue to apply through the estimated expiration dating period. As stated in the FDA *Draft Guidance on Stability Testing* (13), an expiration dating period assigned in this manner should always be justified and supported by accelerated test data and is considered tentative until confirmed through full long-term stability data from at least three production batches reported through annual reports. For known stable products, a more flexible approach is taken. According to the WHO guideline (15), one may directly assign a 24-month shelf-life to a product provided that the active ingredient is stable i.e., stability studies have been performed per tabulated accelerated test conditions for Zones II and IV with no significant changes; supporting data indicate that similar formulations have been assigned a shelf-life of 24 months or more; and the manufacturer continues to perform real-time studies until the proposed shelf-life has elapsed. For products (simple dosage forms) covered under ANDAs, the FDA also permits a direct assignment of a shelf-life as long as 24 months at labeled storage conditions if the accelerated stability data at 0, 1, 2, and 3 months and available long-term stability data are satisfactory (12). CPMP guideline QWP/556/96, however, does not follow this approach, and suggests a statistical analysis of real-time data for the determination of shelf-life, even for existing drug substances and products (13).

How the actual expiration date is calculated from the expiration dating period determined from the statistical analysis described above is also of importance. The FDA draft guidance and CPMP/QWP/486/95 both state that the computation of expiration period of the drug product should begin no later than the time of release of the batch (12, 13). The date of release generally should not exceed 30 days from the production date regardless of packaging date (12). If the release date of the lot fails the 30-day test, a different standard applies in fixing the expiration period. In such cases, the expiration date is calculated from within 30 days of the manufacture of the lot, rather than from the release date (12, 13, 21). If the expiration date includes only a month and year, the product should meet specifications through the last-day-of-that-month guidance (21). The data generated in support of the assigned expiration dating period should be from long-term studies under the storage conditions recommended in the labeling (12).

Arrhenius analysis, described below, of multitemperature data cannot be used alone to set a definitive shelf-life

at a different temperature than that for which long-term data are available. This is primarily because discrepancies in degradation mechanisms at different temperatures makes the Arrhenius law invalid for prediction of a definitive shelf-life from accelerated data. Although Arrhenius analysis is not used as a primary method for proposing a tentative expiration dating period based on accelerated data, application of this analysis to accelerated data can be used as supportive data in conjunction with extrapolation of long-term data. As described below, Arrhenius analysis can be used to anticipate the impact of storage condition or climate zone on the expiration dating interval.

IMPACT OF STORAGE CONDITION OR CLIMATIC ZONE ON EXPIRATION DATING INTERVAL

Arrhenius analysis of a given degradation process yields a relationship between temperature and rate constant. The results of such an analysis can be useful in predicting the impact of changes in storage conditions or climatic zone on expiration dating interval of a given drug-product. In particular, Arrhenius analysis can be used to predict the relationship between the expiration dating period and the label storage conditions. In practice a given formulation and container/closure system may have different expiration periods assigned to them, depending on where, i.e., in which "climate zone," they are being marketed. The Arrhenius relationship between temperature and rate constant is derived below.

For zero-order processes, by which many chemical reactions can be modeled, the rate of disappearance of the reactant A is constant and independent of its concentration, as shown in Eq. 1:

$$-dA/dt = k \quad (1)$$

Solving Eq. 1 yields Eq 2:

$$A = A_0 - kt \quad (2)$$

where,

A = the amount of A remaining at time t ,
 A_0 = the initial amount of A, and
 k = rate constant.

For reactions following zero-order kinetics, a plot of A versus t yields a straight line whose slope is equal to $-k$.

For first-order processes, the rate of disappearance of the reactant A is proportional to the concentration of A at any time t , as shown Eq. 3.

$$-dA/dt = kA \quad (3)$$

The solution of the Eq. 3 yields Eq. 4:

$$\ln A/A_0 = -kt \quad (4)$$

or

$$\ln A = -kt + \ln A_0$$

For stability data that follows first-order kinetics, a plot of $\ln A$ versus t will yield a straight line whose slope is k . The rate constant k , in almost all cases, is a function of the temperature T . For most pharmaceutical products, as T is increased, the rate constant and, therefore, the rate of degradation increases. This is the basis for the well known Arrhenius relationship that states that for a given chemical reaction, the empirical relationship between k and T may be described as in Eq. 5:

$$k = b_0 e^{-E/RT} \quad (5)$$

or

$$\ln k = \ln b_0 - E/RT$$

where,

T = Kelvin temperature,

E = activation energy,

R = ideal gas constant, and

b_0 = constant depending on the molecule of interest.

If a particular kinetic process follows Arrhenius' Law, then a plot of $\ln k$ versus $1/T$ will yield a straight line with a slope of E/R .

A good example of the application of Arrhenius analysis is a pharmaceutical product whose shelf-life is limited by degradation of the active ingredient A . Using stability-indicating assays, the loss of A with time at 25°C has been shown to follow zero-order kinetics between 100 and 90% of the labeled amount. In addition, data from accelerated studies at 40, 50, and 60°C show the same zero-order behavior. If the rate constants from the 25, 40, 50, and 60°C experiments follow Arrhenius' Eq. 5, then from the straight line plot of $\ln k$ vs. $1/T$ for component A in this matrix, the rate constant at any temperature in the data range may be obtained by interpolation. Thus, knowing k for any temperature and the time to be spent at that temperature, the stability performance may be calculated by Eq. 2. In other words, Arrhenius analysis can be used to predict

an expiration date at any temperature owing to storage or climatic zone under which the Arrhenius behavior is valid. Although useful for obtaining an understanding of the impact of temperature changes on expiration dating, Arrhenius analysis breaks down when the degradation mechanisms occurring at one temperature are different from the degradation mechanisms occurring at other temperatures.

Grimm has used the Arrhenius relationship to determine "predictive factors" that can be used to predict the shelf-life at long-term storage in various climate zones from accelerated data (14). For example, the degradation rate at 40°C can be determined by multiplying the time it takes the drug to degrade by 5% at 25 or 30°C by "predictive factors" for those temperatures. Using an activation energy of 83 kJmole⁻¹ Grimm derives predictive factors of 5 and 3.3 for 25 and 30°C, respectively. Obviously, the use of "predictive factors" is only an approximation and breaks down when Arrhenius behavior at different temperatures is not followed.

Impact of Post-Approval Changes on Expiration Dating Period

Often, after a pharmaceutical drug product and its associated dating period and storage condition have been approved, there is a desire to change some aspect of the product (e.g., production process, formulation, packaging, etc.). When a postapproval change occurs, the expiration dating period approved for the original product must be justified for the product after the postapproval change. To justify an expiration date after a postapproval change has been made, various amounts of new or different stability testing are required. Since the last edition of this article, there has been significant activity in the development of new regulations and refinement of existing regulations corresponding to stability testing required for postapproval changes.

The *ICH Topic Q1C; Stability Testing: Requirements for New Dosage Forms* is an annex to the parent ICH guidance (issued 5/1997) Q1A and addresses the recommendations for the data that should be submitted regarding stability of new dosage forms by the owner of the original application after the original submission for new active substances and medicinal products. In the United States, the FDA has issued *Scale-Up and Post-Approval Changes* (SUPAC) guidelines that dictate the stability testing requirements for various postapproval changes for U.S. filings. The available SUPAC guidances are listed below (23):

1. SUPAC-IR: Immediate-Release Solid Oral Dosage Forms: Scale-Up and Post-Approval Changes: Chemistry, Manufacturing and Controls, In Vitro Dissolution Testing, and In Vivo Bioequivalence Documentation (Manufacturing Equipment Addendum Issued 1/1999).
2. SUPAC-MR: Modified Release Solid Oral Dosage Forms Scale-Up and Postapproval Changes: Chemistry, Manufacturing and Controls: In Vitro Dissolution Testing and In Vivo Bioequivalence Documentation (Issued 10/6/97, Manufacturing Equipment Addendum Issued 1/1999).
3. SUPAC-SS: Nonsterile Semisolid Dosage Forms; Scale-Up and Post-Approval Changes: Chemistry, Manufacturing and Controls; In Vitro Release Testing and In Vivo Bioequivalence Documentation (Issued 5/1997; Posted 6/16/1997, Addendum Issued 12/1998).

In Europe, two regulations have been introduced to address “variations” to medicinal products, Regulation (EEC) No. 541/95 and 542/95. For the implementation of the procedures set out by these regulations, a number of guidances have been prepared and an application form for a variation to a marketing authorization has been issued.

In the United States, the approach for determination of stability testing required for a given change follows a tiered approach, with more additional stability data obviously being required for more significant postapproval changes (SUPAC reference). Table 1, reproduced from the

FDA Guidance on Stability Testing, describes the five stability data package types required to support a postapproval change.

For each type of postapproval change, the above table is used to help determine what type of Stability Data Package should be filed. A discussion of the type of Stability Data Package necessary for different changes is found in the FDA Draft Guidance for Stability Testing (12) and dosage form-specific information is available in the SUPAC guidances listed above. For certain changes no prior approval is needed, and a Changes-Being-Effectuated supplement can be filed. This is not the case in Europe, where all postapproval changes require an amendment to be approved before marketing medicinal product manufactured with post-approval change.

EXTENSIONS OR REDUCTIONS IN EXPIRATION DATING

Often after extensive stability data have been collected, there is a desire to change the expiration dating of a product. In particular, the available stability data support either an extension or a reduction in the expiration date approved in the original filing. Changes in expiration dating is covered in the FDA guidance.

For example, the methods for obtaining an extension is outlined in the FDA guidance (12):

Table 1 Stability data package types to support a postapproval change

Stability data package	Stability data at time of submission	Stability commitment
Type 0	None	None beyond the regular annual batches
Type 1	None	First (1) production batch and annual batches thereafter on long-term stability studies
Type 2	Three months of comparative accelerated data and available long-term data on 1 batch ^a of drug product with the proposed change	First (1) production batch ^b and annual batches thereafter on long-term stability studies ^c
Type 3	Three months of comparative accelerated data and available long-term data on 1 batch ^a of drug product with the proposed change	First (3) production batch ^b and annual batches thereafter on long-term stability studies ^c
Type 4	Three months of comparative accelerated data and available long-term data on 3 batches ^a of drug product with the proposed change	First 3 production batch ^b and annual batches thereafter on long-term stability studies ^c

^aPilot scale batches acceptable.

^bIf not submitted in the supplement.

^cUsing the approved stability protocol and reporting data in annual reports.

1. Can be described in an annual report if criteria set forth in the approved protocol are met. In this case, the extension of the expiration dating period must be based on full long-term stability data obtained from at least three production batches (21 CFR 314.70).
2. A prior approval supplement is necessary to extend a tentative expiration date based on three pilot-scale batches. The expiration dating remains tentative until confirmed with full long-term data from at least three production batches.

The methods for shortening an expiration date is through a Changes-Being Effected supplement (21 CFR 314.70 or 21 CFR 601.12).

UNRESOLVED ISSUES FOR THE NEW MILLENNIUM

Two major issues still require attention: first, complete harmonization of stability testing requirements throughout the world remains to be achieved. In particular, benefits could be obtained by harmonizing the "stress" testing requirements for different ICH member countries, complete harmonization of stability testing requirements for all Zone III/IV countries, and more extensive harmonization of stability testing conditions between Zone III/IV countries, where 30C/70%RH is the long-term storage condition for stability studies, and ICH member countries, where 30C/60%RH is the intermediate storage condition. The second unresolved issue is worldwide harmonization of label storage statements. Because the ultimate objective of a stability study is to predict a product's shelf-life at a particular label storage condition, it makes sense that label storage statements be harmonized much the way stability testing requirements have been harmonized. Unfortunately, this is not the case. Q1A suggests that labeling be based on each country's requirements. These requirements are different for most countries. For example, label statements in the United States satisfy the USP, whereas in Europe, no labeling is required. In Japan, labeling is necessary only if the product's stability is less than 3 years. In the WHO guidance, labeling is also defined by the requirements of the country. As can be seen, harmonization of label storage statements still needs to be accomplished. More thorough harmonization of stability testing requirements throughout the world and worldwide harmonization of label storage statements is highly desirable to streamline stability testing programs designed to support a global marketplace.

CONCLUSIONS

Worldwide harmonization of stability testing requirements has made significant progress, but it is still not complete (e.g., labeling requirements are country-specific). In the last decade, the ICH guidances and complementary regional guidelines have significantly enhanced the level of harmonization of stability testing requirements for Europe, Japan, and the United States. The WHO guideline for stability testing of pharmaceutical products containing well established drug substances in conventional dosage forms and the MERCOSUR guidance have begun to accomplish harmonization of stability testing requirements in Zone III/IV. There is still a considerable amount of harmonization to be achieved in Zone III/IV countries. As Zone III/IV countries continue to harmonize, it will be interesting to see whether a new intermediate condition is adopted by the ICH that replaces 30C/60%RH, which would allow worldwide harmonization of testing requirements to support determination of expiration dating periods for each of the four climate zones of the world.

EXPERT SYSTEMS IN PHARMACEUTICAL PRODUCT DEVELOPMENT

Raymond C. Rowe

Ronald J. Roberts

AstraZeneca, Macclesfield, Cheshire, United Kingdom

INTRODUCTION

The process of formulation, whether it be for oral products (e.g., tablets and capsules), parenterals [e.g., intravenous (iv) injections], or any one of the myriad of pharmaceutical products, is generically the same. The process begins with some form of product specification and ends with the generation of one or more formulations that meet the requirements. Although the formulation consists of a list of ingredients and their proportions together with some processing variables where appropriate, the specification can vary considerably from one application to another. In some cases it may be very specific, expressed in terms of a performance level when subjected to a specific test, or quite general. It may also contain potentially conflicting performance criteria that the formulator may need to redefine in the light of experience. Figure 1 shows a typical formulation process broken down into its constituent tasks and subtasks (1).

In designing a formulation, the formulator must take into account the properties of the active ingredient as well as possible chemical interactions between it and the other ingredients added to improve processability and product properties since these may result in chemical instability. There may even be interactions between added ingredients, leading to physical instability. Commercial factors as well as the policy of the industry toward ingredient usage are important influences, as are production factors in the intended markets. The formulator may also routinely access databases on previous formulations as well as make use of mathematical models. During the formulation process, specific tests may need to be run to evaluate the properties of the proposed formulation and an analysis of unexpected results may lead to an adjustment of the ingredients and/or their levels.

TECHNOLOGY

There is a wide divergence of views as to what defines an expert system. Examples include the following:

1. "An expert system is a knowledge-based system that emulates expert thought to solve significant problems in a particular domain of expertise" (2).
2. "An expert system is a computer program that draws on the knowledge of human experts captured in a knowledge base to solve problems that normally require human expertise" (3).

In its simplest form, an expert system has three major components: 1) an interface, a monitor, and keyboard that allow two-way communication between the user and the system; 2) a knowledge base where all the knowledge pertaining to the domain is stored; and 3) an inference engine where the knowledge is extracted and manipulated to solve the problem at hand. Inferencing strategies may be either forward chaining, which involves the system reasoning from data and information gained by consultation from the user to form a hypothesis, or backward chaining, which involves the system starting with a hypothesis and then attempting to find data and information to prove or disprove the hypothesis. Both strategies are included in most expert systems.

Knowledge in any domain takes the form of facts and heuristics; the former being valid, true, and justifiable by rigorous argument, the latter (often referred to as rules of thumb) being the expert's best judgment in any particular circumstance and hence justifiable only by example. Associated with these are the terms data and information, the former referring to facts and figures, the latter being data transferred by processing such that the data are meaningful to the person receiving the information. Knowledge can, therefore, be regarded as information combined with heuristics and rules. It is the objective of the knowledge engineer to acquire or elicit this knowledge and structure it in a computer-readable format.

Knowledge acquisition is probably one of the most difficult stages in the development of an expert system. It is both time-consuming and tedious as well as being expensive and often difficult to manage. However, it is a necessary element in the building of an expert system and, if done well, will undoubtedly lead to potentially useful systems. The basic model of knowledge acquisition is one of a team process whereby the knowledge engineer

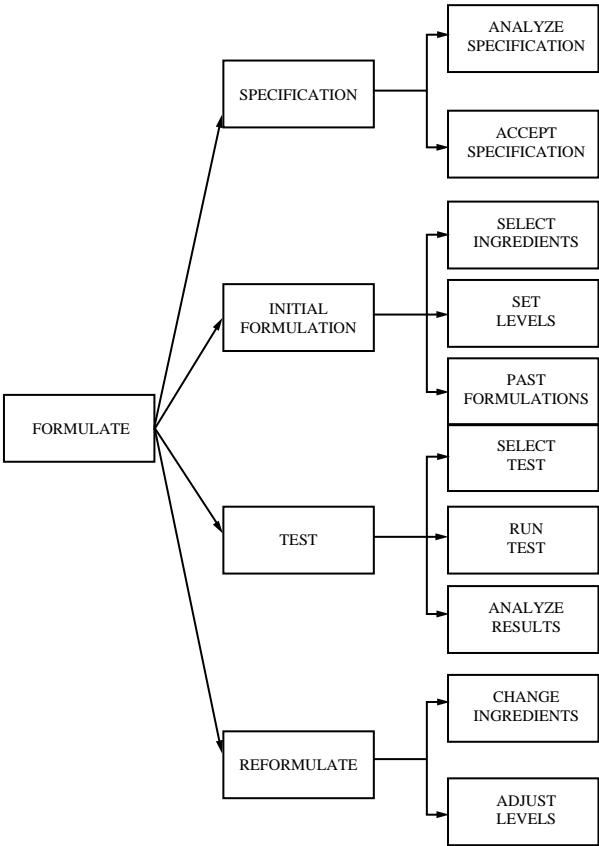

Fig. 1 Tasks and subtasks in the formulation process. (From Ref. 1.)

mediates between the expert(s), the users, and the knowledge bases. The knowledge engineer must acquire or elicit knowledge from not only the expert(s) but also from all the other potential sources, including written documents (research reports, reference manuals, and operating procedures policy statements) as well as consultants, users, and managers. In the case of experts, knowledge is usually acquired through face-to-face interviews. While this process is tedious and can place great demands on both the expert and knowledge engineer, it requires little equipment (e.g., tape recorder or notebook), is highly flexible, and often yields a considerable amount of useful information. At all times, there must be empathy between the participants and in many cases it is helpful to have two knowledgeable engineers present at the interview.

A technique that is often used in the acquisition process is the rapid prototyping approach. In this approach, the knowledge engineer builds a small prototype system as early as possible. This is then shown to both the expert and user, who can suggest modifications and additions. Here the system grows incrementally as more information and

knowledge are gained. This methodology has been used successfully in the development of systems for the formulation of pharmaceuticals.

Once acquired, there are many ways of representing the knowledge in the knowledge base, including production rules, frames, semantic networks, decision tables, and trees and objects (2). Probably the most common methodology is the production rule, which expresses the relationship between several pieces of information by way of conditional statements that specify sections under certain sets of conditions, for example:

IF	(condition 1)
AND	(condition 2)
OR	(condition 3)
THEN	(action)
UNLESS	(exception)
BECAUSE	(reason)

Each rule implements an autonomous piece of knowledge and is easy to understand. Unfortunately, complex knowledge can require large numbers of rules, causing the system to become difficult to manage. The decision as to which method of knowledge representation should be adopted is dependent primarily on the complexity of the domain.

Expert systems can be developed using either conventional computer languages, special purpose languages, or with the assistance of development shells or tool-kits. Conventional languages such as PASCAL and C have the advantages of wide applicability and full flexibility to create the control and inferencing strategies required. They also are well supported and easy to customize. However, considerable amounts of time and effort are needed to create the basic facilities.

Specialized languages, such as LISP (a recursive language and the primary one for artificial intelligence research), PROLOG (a language based on first-order predicate logic), and SMALLTALK (an object-orientated language), have been used extensively in the development of expert systems. They have the advantages of applicability and flexibility of the conventional languages but are faster to implement.

Expert system shells and tool kits are sets of computer programs written in either conventional or specialized languages that can form an expert system when loaded with the relevant knowledge. They compromise on applicability and flexibility but allow more rapid development. Many offer basic facilities, including the means to prepare and store knowledge as a set of rules and to make deductions by chaining the rules together in an inferential process.

Shells differ in their secondary characteristics, such as user interfaces, operating speeds, the method of knowledge representation, and the associated algorithmic and arithmetic computational facilities. It is not surprising, therefore, that formulation is a highly specialized task that requires specific knowledge and often years of experience. This kind of expertise is not easily documented and hence, senior formulators often spend considerable amounts of time training new personnel. In addition, retirement or personnel moves can lead to a loss of irreplaceable commercial knowledge. Computer technology in the form of expert systems provides an affordable means of capturing this knowledge and expertise in a documented form available to all.

One such shell of specific importance in product formulation is Product Formulation Expert System (PFES), now termed Formulogic, developed by Logica UK Ltd. Formulogic is a reusable software kernel and associated methodology to support the generic formulation process. It arose from research work during the mid-1980s and is now used for a variety of formulation support tools across a range of industry sectors, most notably pharmaceuticals (4, 5).

Formulogic is designed specifically for building formulation systems. Its formulation capability is generic, i.e., it is not specific to any particular domain. Individual formulation applications are developed using the shell by defining characteristics of the domain and the corresponding approach to formulation. The end result is a decision support tool for formulators that provides assistance in all aspects of the formulation development process. Formulogic provides the expert system developer with the knowledge representation structures that are common to most product formulation tasks so that a new application can be developed rapidly and efficiently. The architecture of Formulogic comprises three levels—the Physical Level, the Task Level, and the Control Level.

The Physical Level contains all the “nuts and bolts” of the formulation domain in a number of information sources, including a database. The Physical Level is accessed from the Task Level via a query interface. The physical net contains the domain knowledge in a number of objects. An object consists of a set of attributes, each of which may have zero or more values. The objects are arranged in a classification hierarchy. Subobjects, which descend from another object, inherit their attributes and values.

The Task Level is where the formulation problem-solving activity takes place. The formulation process is driven via the generation of a hierarchy of tasks. A task represents some well-defined activity. The hierarchy has an indefinite number of task levels. Domain knowledge about the formulation application is distributed throughout

the hierarchy, with more abstract knowledge represented towards the top of the hierarchy and more specific knowledge toward the bottom.

The task decomposition allows the problem-solving process to be largely decoupled between tasks and also facilitates reasoning about subtasks. An important principle is that tasks plan about and directly manipulate only their immediate subtasks. Recursive application of this principle is the key to integrated behavior of a formulation system as a whole. The task tree is built on dynamically, depending upon the specification at hand as the problem-solving process proceeds. This is different to the object hierarchy where the structure is fixed for a particular domain.

Agendas, a particularly important class of objects used for communication between tasks, also are part of the Task Level. Agendas are important because the user exercises control over the formulation process principally through their manipulation. For parallel reasoning and backtracking by the user it is necessary to maintain more than one world. A world contains a formulation object and specification object together with agendas (in other words, a complete description of the state of the formulation process at any one time). Tasks run on a world or set of worlds; it is meaningless for tasks to run without reference to worlds.

Tasks perform their function by the execution of processes. Each task contains several types of processes. The precondition process assesses whether or not the task can play a sensible role in the current context. The action process performs the primary work of the task, which can include scheduling subtasks to be run next. The monitor process executes between each of the subtasks, typically to assess their result. Finally, the postcondition process assesses the success of the task as a whole immediately prior to completion.

Each process consists of a set of production rules; a rule is said to fire if its condition is true and its exception is false. When a rule fires, its action is executed. The reason is for information only and is not interpreted by Formulogic.

Rules are assigned a priority that reflects the order in which they should be considered. When executing a rule set, rules are tried in order until no more rules can fire. To find a suitable rule, Formulogic orders the rules first on priority and then on specificity. The first rule having a true condition and false exception is fired, and its action executed. The process of finding the next rule that can fire then starts all over again. To avoid looping, rules are only allowed to fire once with the same set of variable bindings.

The Control Level is concerned with the mechanics of running the Task Level. It contains no domain knowledge

and requires no design amendment when a new formulation system is built. Although the Task Level decides which tasks need running and the order in which they should run, the Control Level deals with the mechanics of actually running them and of passing control to them.

The typical functionality of a completed application is as follows:

1. The user enters the product specification, which forms the starting point of the formulation. In a tablet formulation, for example, this would consist of the drug details (unless already known to the system) and the dose.
2. Formulogic steps through a series of tasks to select ingredients and determine their quantities based on the product specification. It achieves this by following the rules and other knowledge that have been built into the system during development. An initial formulation is produced.
3. If the system performs reformulation in addition to producing initial formulations, then the user can enter the test results that have been performed on the product. Formulogic will then determine what kinds of problems with the formulation are indicated by the test results. The user can agree with the system's analysis of the problems or modify them as he or she sees fit. It uses the problem summary to make recommendations about what ingredients need to be added or what quantities need to be altered, and again the user can override the recommendations if he or she wishes. Once the user is happy with the recommendations, Formulogic will produce a modified formulation that meets the new requirements.

At any point during a session, the user can ask for an explanation of the results, browse the system's knowledge, or revert to an earlier stage of the process to modify the specification and obtain another formulation. The user can also save formulations (along with their associated product specifications) and generate printed reports.

APPLICATIONS

The first recorded reference to the use of expert systems in pharmaceutical product formulation was by Bradshaw on the April 27, 1989, in the London Financial Times (6), closely followed by an article in the autumn of the same year by Walko (7). Both refer to the work then being undertaken by personnel at ICI/Zeneca Pharmaceuticals (now AstraZeneca), United Kingdom (UK) and Logica UK Ltd. to develop expert systems for formulating pharmaceuticals using Formulogic. Since that time,

several companies and academic institutions have reported on their experiences in this area (Table 1). This article will review these applications.

The Boots System

Although not strictly developed for pharmaceutical formulation, this system has been included since it is the only one known for formulating topicals. It was developed to assist formulators in the formulation of sun care products—a highly skilled occupation requiring 3–4 years of experience to attain a reasonable level of experience.

Implemented with the use of Formulogic, the system, called SOLTAN, uses knowledge captured by interviewing senior formulators. Ingredients, processes, and relationships of the formulation are represented in a way that reflects their groupings and associations in the real world. In addition, existing information sources, such as databases, are presented in a frame-based semantic network that can be manipulated by the problem-solving knowledge of the domain. Tasks are structured in a hierarchy that is built up dynamically depending on the specification at hand as the problem-solving process proceeds. Knowledge about the formulation is distributed throughout the task hierarchy, with strategic knowledge represented toward the top of the hierarchy and tactical knowledge towards the bottom.

The system was originally developed to formulate sun oils (solutions of ultraviolet absorbers in emollients) but has been rapidly extended, with the incorporation of basic emulsion technology, to cover oil-in-water lotions. Subsequently, the system has been further expanded to incorporate water-in-oil, oil-in-water, and water-in-silicone

Table 1 Published applications of product formulation expert systems in pharmaceuticals

Company/institution	Domain	Development tool
Boots Company	Topicals	Formulogic
Cadila Laboratories (India)	Tablets	PROLOG
University of Heidelberg	Aerosols	C/SMALLTALK
	Tablets	
	Capsules	
	Injections	
University of London/ Capsugel	Capsules	C
Sanofi Research	Capsules	Formulogic
Zeneca Pharmaceuticals	Tablets	Formulogic
	Parenterals	
	Film coatings	

creams and lotions. It can now be used to formulate all types of skin care products, not just sun care products (8). The system won second prize in the UK DTI Manufacturing Intelligence Awards in 1991. It is the only system for which the developers have given details of costings and quantitative benefits.

The Cadila System

Cadila Laboratories Ltd. of Ahmedabad, India have developed an expert system for the formulation of tablets for active ingredients based on their physical, chemical, and biological properties (9). The system first identifies the desirable properties in the excipients for optimum compatibility with the active ingredient and then selects those that have the required properties based on the assumption that all tablet formulations comprise at least one binder, one disintegrant, and one lubricant. Other excipients such as diluents (fillers) or glidants are then added as required.

Knowledge is acquired through "active collaboration" with domain experts over a period of 6–7 months. It is structured in two knowledge bases in a spreadsheet format. In the knowledge base concerning the interactions between active ingredients and excipients, the columns represent the properties of the excipients with descriptors of "strong," "moderate," and "weak." The rows represent the properties of the active ingredients, e.g., functional groups (primary amines, secondary amines, highly acidic etc.), solubility (very soluble, freely soluble, soluble, sparingly soluble, slightly soluble, very slightly soluble, insoluble), density (low, moderate, high), etc. Each cell in the spreadsheet then represents the knowledge of the interaction between the various properties. Production rules derived from this knowledge are in the following forms:

IF	(functional group of active ingredient is "primary/secondary amine")
THEN	(add "strong" binder)
AND	(add "strong" disintegrant)
AND	(avoid lactose)

or

IF	(functional group of active ingredient is "highly acidic")
THEN	(add "moderate" binder)
AND	(add "moderate" disintegrant)
AND	(avoid starch)

or

IF	(active ingredient is soluble)
THEN	(add "weak" binder)
AND	(add "weak" disintegrant)

A similar approach is used for the knowledge base concerning the excipients, where the columns now represent details (e.g., name, minimum, maximum, and normal concentrations) of the excipients and the rows their properties (e.g., type and the descriptors—strong, moderate, and weak). Each cell in the spreadsheet then represents the name and the amount to be added to the formulation.

The system, written in PROLOG, is menu-driven and interactive with the user. The user is first prompted to input all the known properties of the new active ingredient. If the properties have descriptors, the user can select the appropriate ones. All information can be edited to correct errors. The expert system then consults the knowledge bases, suggesting compatible excipients and a formulation. If the latter is unacceptable, the system provides alternative formulations with explanations. All formulations can be stored along with explanations, if necessary. The user is able to update the knowledge base via an interface with a spreadsheet. An example of a formulation generated for the analgesic drug paracetamol, or acetaminophen, (dose 500 mg) is shown in Table 2. It is interesting to note that the diluent/filler is unnamed; it can be assumed that it will not be lactose since the relevant production rule indicates that there would be an interaction with the secondary amine in paracetamol. Furthermore, an examination of formulations on the market indicates that

Table 2 An example of a tablet formulation for the analgesic drug paracetamol as generated by the Cadila system

<i>Input</i>		
Dose	500 mg	
Functional group	Secondary amines	
Solubility	Sparingly soluble	
Density	Moderate	
Hygroscopicity	Moderate	
Dissolution	Slow	
Desired tablet weight	570 mg	
<i>Output</i>		
Active agent	Paracetamol	500.0 mg
Binder	Pregelatinized starch	43.7 mg
Disintegrant	Sodium starch glycolate	5.0 mg
Lubricant	Stearic acid	2.5 mg
Diluent/filler	Unnamed	20.0 mg
	Tablet weight	571.2 mg

(From Ref. 9.)

none contain lactose and that some contain mixtures of maize starch, sodium starch glycolate, stearic acid, magnesium stearate, and microcrystalline cellulose, adding further credibility to the Cadila system.

When first implemented, the prototype system had 150 rules, but this has expanded rapidly to approximately 300 rules in order to increase reliability. This is expected to increase further over time. The system is regarded as being highly successful, providing competitive advantage to the company (9).

The Galenical Development System

The Galenical Developmental System (GSH) was developed by personnel in the Department of Pharmaceutical and Biopharmaceutics and the Department of Medical Informatics at the University of Heidelberg, Germany. It is designed to provide assistance in the development of a range of formulations, starting from the chemical and physical properties of an active ingredient. The project was initiated in 1990 under the direction of Stricker (10), and in the interim has been extensively revised and enhanced (11, 12). Originally implemented using object-oriented C on a workstation, the system was recently upgraded using SMALLTALK V running under the Windows operating system on a personal computer.

Various forms of knowledge representation are used depending on the type of knowledge. Knowledge about objects (e.g., functional groups in the active ingredient, excipients, processes, etc.), their properties, and relationships are represented in frames using an object-oriented approach. Causal relationships are represented as rules, functional connections as formulas, and procedural knowledge as algorithms. The system currently has knowledge bases for aerosols, IV injection solutions, capsules (hard-shell powder), and tablets (direct compression). Each knowledge base incorporates information on all aspects of that dosage formulation (e.g., properties of the excipients to be added, compatibility, processing operations, packaging, and containers and storage conditions), with each aspect given a reliability factor (Sicherheitsfaktor) to indicate its accuracy/reliability. In the original version of the system values for each factor varied between 0 and 9 (10); however, values between 0 and 1 are used currently. The values are propagated using the arithmetic minimum rule and are not used for any decisions. They only serve as indicators of the accuracy/reliability of the knowledge.

The approach used in the system is the decomposition of the overall process into individual distinct development steps, with each step focusing on one problem associated

with a subset of its specifications or constraints for the formulation. A problem is considered solved if its predicted outcome satisfies its associated constraints. The problems are worked through in succession, with care being taken that any solution should not violate any constraints from previous steps. For simplicity, the developers imposed a predefined ordering onto the development steps, providing a backtracking mechanism to go back to a previous step or abort. This ordering minimizes dependency between development steps, which might result in an action causing a constraint previously satisfied to be violated. It also reduces the complexity of the problem to be solved.

The procedural model for one development step (e.g., for the choice of an excipient) is shown in Fig. 2. In any development step the first decision is whether or not to proceed with any action since the problem may have already been solved in previous steps. This is done by comparing the predicted or relevant properties of the current formulation with the initial specification. If the answer is negative, then further action is required; if positive, the problem has been solved. Once this has been decided, actions need to be defined and ranked. Knowledge for this is by means of hierarchically structural rule sets to form a decision tree where each leaf node consists of a subgroup of actions and each branch a rule. The rules in a rule set are ordered as the simplest and most straightforward way of handling conflict. Ranking numbers are used as the basis for the selection strategy. The concept is to search for the best alternative in terms of the highest score, these being the sum of the values of the constants to be resolved within the development step (e.g., solubility, compressibility, etc.) and their weights indicating their respective importance (11, 12). It should be noted that this method of ranking is different from that used originally by Stricker et al. (10), where the lowest score was regarded as the best alternative.

Once the action is selected, the decision is checked in terms of whether or not the measure has adverse effects on the active ingredient in terms of physical or chemical incompatibility. This does not necessarily mean a rejection of the action since knowledge of compatibility is generally of a qualitative nature with little quantification to denote severity. Hence, the overall decision is left to the user.

The amounts of excipients to be used are calculated by formulae with rule-based mechanisms for selecting the appropriate formula. A rule-based mechanism is also used to determine the appropriate function for predicting the property of the intermediate formulation. This is necessary for checking whether or not the original specifications have been satisfied and the action is successful. If

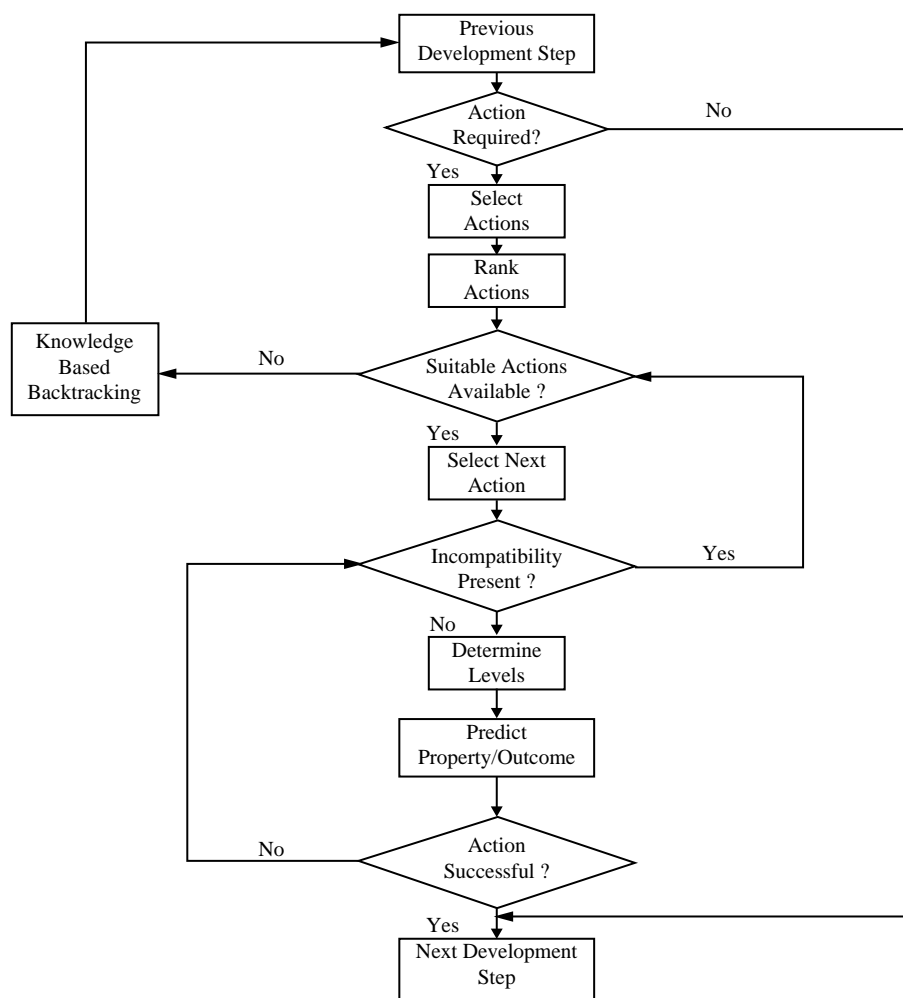

Fig. 2 Procedural model for a development step as used in GSH. (Modified after Ref. 12.)

negative, the chosen action is rejected and the next action in the ranking is tried. It is possible that none of the ranked actions is successful. If this is the case, then knowledge-based backtracking is used to determine which of the previous development steps to return to. Usually, background pharmaceutical knowledge is applied to determine why the current development step was unsuccessful, and a new development step that can solve the root cause of the problem is chosen.

In any expert system, explanations of the decisions made are important, both for instruction of the user and for maintenance of the system. Explanations in GSH take several forms. There are explanations for the development steps and their ordering provided by the designer of the knowledge base. Detailed explanations of the rules activated, formulae used, or individual scores of actions can be generated if required, and canned text and literature references are provided for general knowledge.

A simplified task structure for generating an iv injection solution is shown in Fig. 3. The input to the system includes all the known properties of the active ingredient to be formulated (e.g., solubility, stability, impurities, pK_a , presence/absence of functional groups, etc.) with user-defined labels that relate the specific drug property to the required product property. Use of the system results in the production of four packages—the product formulation, the production method, the recommended packaging and storage conditions, and predicted product properties. All the outputs are provided with reliability factors. An example for an IV injection solution of the cardiac drug digoxin is shown in Table 3, and an example for a hard gelatin capsule of the antifungal drug griseofulvin is shown in Table 4. Comparison of a 0.1 mg. commercial formulation of digoxin with that shown in Table 3 indicates that the same cosolvent is used (1,2-propandiol, presumably to enhance solubility) and ethanol. However,

Fig. 3 Structure of the expert system described by Stricker et al. (10) for the formulation of intravenous injection solutions.

the commercial formulation is more sophisticated since it also contains a buffer (disodium hydrogen phosphate/citric acid).

At present, knowledge bases for aerosols, IV injection solutions, hard gelatin capsules, and direct compression tablets have been completed. Other knowledge bases for coated forms, granules, freeze-dried formulations, and pellets are in different stages of development. Trials have demonstrated that the system proposes formulations that are acceptable to formulators, and in December 1996, the system was first introduced for field trials in a pharmaceutical company.

The University of London/ Capsugel System

This system is designed to aid the formulation of hard gelatin capsules (13–15). It was developed as part of a Ph.D. program by Lai, Podczek, and Newton at the School of Pharmacy, University of London, and was

supported by Daumesnil of Capsugel, Switzerland, together with personnel from the University of Kyoto, Japan and the University of Maryland, United States. The system (Fig. 4) is unique in that its knowledge base is broad and contains the following:

1. A database of literature references associated with the formulation of hard gelatin capsules, which is permanently updated through monitoring of current literature.
2. Information on excipients used and their properties. This database currently contains information on 72 excipients and is frequently updated. Data can be retrieved via a menu.
3. An analysis of marketed formulations from Germany, Italy, Belgium, France, and the United States. This is used to identify trends in formulation and identify guidelines on the use of excipients. Currently, the database contains information on 750 formulations of 250 active ingredients. It is frequently updated and data can be retrieved via a menu.

Table 3 An example of an intravenous injection solution formulation for the cardiac drug digoxin as generated by GSH

<i>Formulation</i>			
Active	Digoxin	0.1 mg	
Solvent 1	1,2-Propandiol	0.5 mL	
	Water for injection to	1.0 mL	
<i>Packaging</i>			
Brown glass ampules			
<i>Product properties</i>			
Properties	Specification	Actual	R.F. ^a
Active (mg)	0.095	0.098	1.0
Volume (mL)	1.0	1.0	1.0
pH	3–9	7.0	1.0
Freezing point depression (°C)	0.5–20	13.2	0.8
Shelf life at 25°C (years)		5.0	1.0
Decomposition at 25°C (mol)		1.8	0.7

^aR.F., reliability factor.
(From Ref. 10.)

- Experience and nonproprietary knowledge obtained over a period of 18 months from a group of industrial experts from Europe, the United States, and Japan.
- Results from statistically designed experiments that identify factors that influence the filling and in vitro release performance of model active ingredients.

The system uses production rules with a decision tree implemented in C, coupled with a user interface through which the user can access both the databases and develop new formulations. To assist in collecting all necessary input data, a questionnaire has been designed. Called the expert system input package, it requires information on the physical properties of the active ingredient (e.g., dose, particle shape,

particle size, solubility, wettability, adhesion to metal surfaces, melting point, and bulk density), compatibility of the active ingredient with excipients (e.g., fillers/diluents, disintegrants, lubricants, glidants, and surfactants), and properties of excipients used by the user and manufacturing conditions (e.g., capsule sizes, fill weights, densification techniques, granulation techniques) used by the user.

From this data the system uses a variety of methods to evaluate and predict properties of mixtures of the active ingredient and the excipients. For instance, it uses Carr's compressibility index (16) to predict the flow properties that are used to give an indication of the ability to produce a uniform blend, and the Kawakita equation (17) to predict a maximum in the volume reduction of the powder

Table 4 An example of a hard gelatin capsule formulation for the antifungal drug griseofulvin as generated by GSH

<i>Formulation</i>

<i>Production process</i>		
High shear mixer for deagglomeration, premix, and main mix.		
Add lubricant, planetary mixer at 12 rpm for 3 min.		
Capsule-filling machine type 1.		
<i>Packaging</i>		
Foil blisters (PVC and aluminum foil)		

(From Ref. 12.)

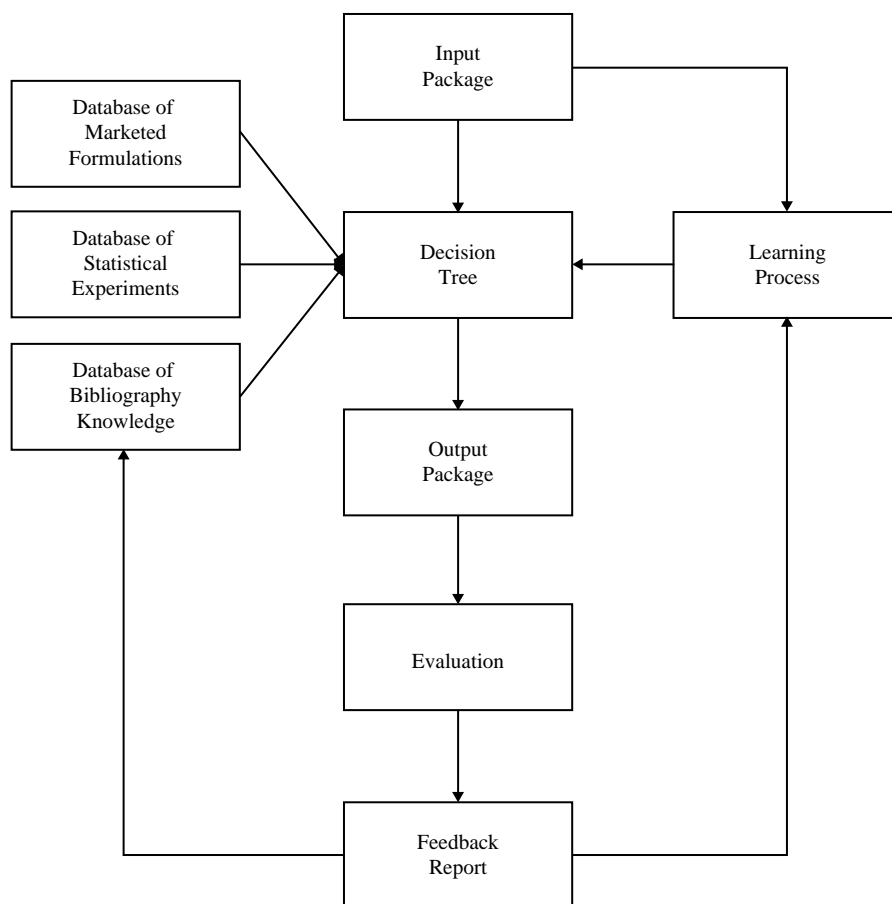

Fig. 4 Structure of the University of London/Capsugel system as described by Lai et al.

achievable by the application of low pressure. The packing properties are obviously important to give the volume that a given weight of powder occupies in order to indicate the size of capsule shell that can be used. When wet granulation is offered as the preferred method of densification, the system only offers advice on the choice of a granulating liquid and binder; no choice on the granulation procedure is offered.

The system provides an output package that includes a formulation (Table 5) with any necessary powder processing and filling conditions, the required capsule size, a statistical design to quantitatively optimize the formulation, specification of excipients used, recommended tests to validate the formulation, and a complete documentation of the decision process.

An interesting addition to the system is a semiautomatic learning tool. This monitors user habits and collects data about the use of excipients. Statistical analysis is performed on these data, allowing agreed alterations to be made to the database. The user is also asked to reply to a

questionnaire regarding the recommended formulation and its performance. The data are analyzed by the expert system founder group, and provide the background for further alterations and developments.

Field trials have proved that the system does provide reasonable formulations (18).

The Sanofi System

Personnel at the Sanofi Research Division of Philadelphia recently developed an expert system for the formulation of hard gelatin capsules based on specific preformulation data of the active ingredient (19). Using Formulogic, the system generates one first-pass clinical capsule formulation with as many subsequent formulations as desired to accommodate an experimental design. The latter are produced as a result of the user overruling decisions made by the system.

Knowledge acquisition is obtained by meetings between formulators, with a knowledge engineer present as a

Table 5 An example of a hard gelatin capsule formulation for a model drug as generated by the university of londoncapsugel system

<i>Tablet properties (inputs)</i>

consultant. Meetings are limited to 2 h, with minutes being taken and reviewed by all attendees. Meetings are specific to one topic defined in advance. A rapid prototyping approach is used to generate the expert system.

Knowledge in the system is structured using the strategies implemented in Formulogic, i.e., objects and production rules. The latter are as follows:

Tasks are scheduled dynamically. An outline of the task structure used is given in Fig. 5.

IF	(electrostatic properties of a drug are problematic)
THEN	(add glidant)
UNLESS	(glidant has already been added)

The user is first prompted to enter specified preformulation data on the active ingredient (e.g., acid stability, molecular weight, wettability, density, particle size, hygroscopicity, melting point, solubility, etc.) and known excipient incompatibilities together with the required dose. At the initial formulation task, the capsule size is selected together with the process and milling requirements. The excipient classes are selected, with some excipients being excluded, others prioritized, and their amounts determined. At the display reports task, three reports are provided, one providing the preformulation data as given, the second giving the recommended formulation, including the amounts of the excipients and processing/milling requirements, and the third providing the explanation of the decisions and reasoning used by the system. On the

first-pass through the system, the selection of the possible processing, milling, and excipient options are automatic. On subsequent passes, the selections are optional, allowing the user to generate a number of formulations.

An example of a formulation generated by this system, for the nonsteroidal anti-inflammatory drug naproxen, is given in Table 6. This example, as well as others, was considered acceptable by experienced formulators for manufacture and initial stability evaluation.

Unfortunately, the authors (19) do not provide any further details on the state of the system except to imply that formulation evaluation and preformulation tasks could be accommodated with the possible development for other formulation types such as tablets, liquids, and creams.

The Zeneca Systems

Work on expert systems within ICI/Zeneca Pharmaceuticals (now AstraZeneca) began in April 1988, with the initiation of a joint project between the Pharmaceutical and Corporate Management Services departments to investigate the use of knowledge-based techniques for the formulation of tablets. Since that time, work has proceeded with the successful development of expert systems for formulating tablets, parenterals, and tablet film coatings. All have been implemented using Formulogic from Logica UK Ltd., although elements of the system developed for

Fig. 5 Task structure for the formulation of hard gelatin capsules as used by Bateman et al. (19).

tablet film coatings were originally prototyped using a rule induction tool to produce decision trees.

Delivery of the first usable system for tablet formulation was in January 1989 (20, 21). All the knowledge was acquired from two primary experts in the field of tableting—one with extensive heuristic knowledge and the other with extensive research knowledge—and structured into Formulogic using specialist consultancy support. Consultancy time for the initial system was in the order of 30 man days, 20% of which was involved in three 2-day visits to the laboratories, incorporating three 90-min interviews with the experienced formulator plus members of the research group, the demonstration of prototype systems, and the validation of the previously acquired knowledge with the expert and other members of the department. Sixty percent of the time was involved in system development and 20% in writing the final report.

After commissioning and extensive demonstration to management and formulators throughout the company during 1989, the system was enhanced by the addition of a

link to a database in January 1990, and the installation of a formulation optimization routine in September 1990. A major revision was initiated in February 1991, following a significant change in formulation practice. Total consultancy time for these enhancements was of the order of 30 man-days. In August 1991, the system was completed and handed over to the formulators both in the United Kingdom and the United States.

The completed system is shown in Fig. 6 (20). It is divided into three stages: 1) the entry of the data, product specification, and strategy; 2) the identification of the initial formulation; and 3) the formulation optimization as a result of testing the initial formulation. The sequence is as follows:

1. The user enters all the relevant physical, chemical, and mechanical properties (e.g., solubility, wettability, compatibility with excipients, and deformation behavior) of the new active ingredient to be formulated into the database. The data may be

Table 6 An example of a hard gelatin capsule formulation for the antiinflammatory drug naproxen as generated by the system described by Bateman et al.

<i>Selected drug properties (inputs)</i>		
Molecular weight		230.26
Melting point (°C)		155
Solubility in water (mg ml ⁻¹)		0.01
Wettability		Poor
Water stability		Poor
Photostability		Poor
Susceptible to hydrolysis		No
Primary/secondary amines		No
Hygroscopicity		Class 1
Poured density (g cm ⁻³)		0.366
Electrostatic problems		No
Unmilled particle size (μm)		36
<i>Formulation</i>		
Active	Naproxen	100 mg
Diluent	Lactose (hydrous)	224 mg
Disintegrant	Microcrystalline cellulose (PH105)	60 mg
Surfactant	Sodium lauryl sulfate	4 mg
Lubricant	Talc	12 mg
<i>Production information</i>		
Milling	Jet milling of drug	
Capsule	Size 0 colored opaque	
Process	Direct blend	
<i>Explanation log</i>		
A colored opaque capsule used because drug is unstable to light.		
Drug requires milling as it has a medium particle size and is insoluble.		
A surfactant is required because drug has poor wettability.		

(From Ref. 19.)

numerical or symbolic (e.g., for solubility in water the data can be entered as mg ml⁻¹ or as the descriptors “soluble,” “partially soluble,” “insoluble,” etc. The data are obtained from a series of proprietary preformulation tests carried out on the active ingredient as received (i.e., 5 g of the drug milled to a specified particle size). These tests include excipient compatibility studies whereby the drug is mixed with the excipient and stored under specified conditions of temperature and humidity for one week, the proportion of drug remaining being analyzed by HPLC and expressed as a percentage. The deformation properties essential for the evaluation of compactibility are assessed using yield pressure and strain rate sensitivity measured via a compression simulator (22).

- The user enters the proposed dose of the active ingredient and a target tablet weight is calculated using both a formula determined from an extensive study of

previously successful formulations and certain rules governing minimum weights for ease of handling and maximum weights for ease of swallowing.

- The user selects a strategy dependent on the number of fillers (one or two).
- The system selects the filler(s), disintegrant, binder, surfactant, glidant, and lubricant, and their recommended concentrations based on a combination of algorithms, formulae, and mixture rules governing their compatibility and functionality. Tasks in this process are dynamically scheduled depending on the problem to be solved. If the system is unable to decide between two excipients, both of which satisfy all the embedded rules, then the user is asked to select a preference.
- The recommended initial formulation is displayed, including final tablet weight, recommended tablet diameter calculated compression properties, and all relevant data (Table 7). This is normally printed for inclusion in a laboratory notebook, file, etc. If required,

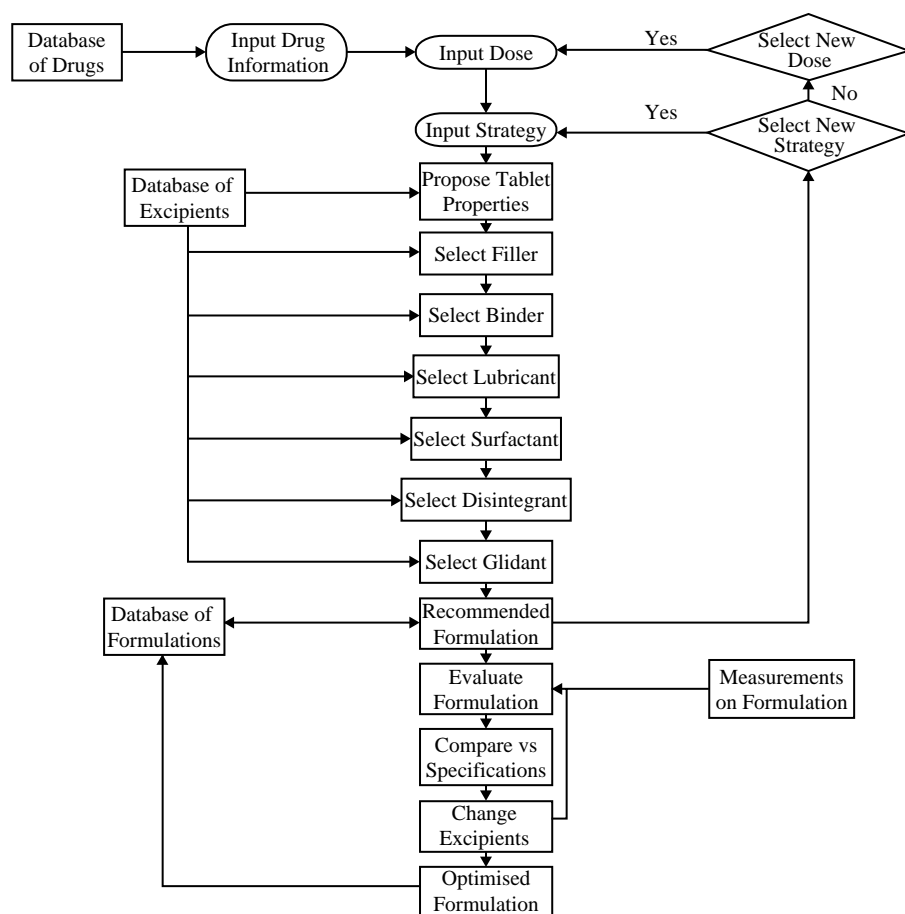

Fig. 6 Structure of the expert system developed by Rowe (20) for the formulation of tablets.

- the data may be stored in a database for future reference, necessary if the formulation optimization route is used.
6. The user enters results from testing tablets prepared using the initial formulation. These may include disintegration time, tablet strength, tablet weight variation, and presence of any defects (e.g., capping, lamination, etc.). The results are compared with specifications, and any problems identified are confirmed with the user. Recommendations for modifications to the formulation are then listed. This routine is fully interactive with the user, who is asked to confirm or contradict/change the advice given.
 7. After agreement is reached, the system modifies the formulation accordingly and displays it as described earlier. This routine may be used as many times as required; each time, the system iterates on the previously modified formulation.

Two “help” routines are embedded in the system, one to provide on-line help in the use of the system, the other to

provide an insight into the rationale behind adoption of the specific rules/formulae/algorithms used. The user is able to browse the knowledge base at will but is not able to edit it without privileged access. Explanations for any recommendations made by the system can be easily accessed, if required. Hypertext links are used throughout. Two screen images from the system are shown in Fig. 7 to illustrate the operation of the system.

The system is well used and is now an integral part of the development strategy for tablet formulation. To date, it has successfully generated formulations for more than 40 active drugs. In many cases, the initial formulations have been acknowledged as being on a par with those developed by expert formulators. Consequently, the formulation optimization routine is now considered redundant and is used very rarely.

Following the successful implementation of the tablet formulation expert system, a request was made for the development of a similar system for parenteral formulations. This project was initiated in April 1992, and

Table 7 Examples of tablet formulations for a model drug as generated by the system described by Rowe

<i>Drug properties (inputs)</i>			
Solubility (mg ml ⁻¹)		0.1

Strain rate sensitivity (%)		20.8	5.1

(From Ref. 20.)

completed in August 1992 (23). The structure of the system is shown in Fig. 8. It is designed for formulating a parenteral for either clinical or toxicological studies in a variety of species (dog, man, mouse, primate, rabbit, or rat) by a variety of routes of administration (iv, intramuscular, subcutaneous, interperitoneal), supplied in either a single or multidose container. Knowledge was acquired from two domain experts using a series of interviews. The sequence is as follows:

1. The user enters all known data on the solubility (aqueous and nonaqueous), stability in specified solutions, compatibility, pK_a , and molecular properties of the active ingredient (molecular weight, log P , etc.). As with the system for tablet formulation, the data may be numerical or symbolic. All relevant properties of additives used in parenteral formulation (e.g., buffers, antioxidants, chelating agents, antimicrobials, and tonicity adjusters) are present in the knowledge base.
2. The selection first attempts to optimize the solubility/stability of the active drug at a range of pH using a variety of formulae and algorithms together with specific rules before selecting a buffer to achieve that

pH. If problems still exist with solubility and stability, then formulation variants (e.g., oil-based or emulsion formulations—not implemented in the present system) are recommended.

3. The system then selects additives, depending on the specification required (e.g., an antimicrobial will only be added if a multidose container is specified or a tonicity adjuster will only be added if the solution is hypotonic). The selection strategy is generally on the basis of ranking with some specific rules.
4. The recommended formulation is displayed with all concentrations of the chosen ingredients expressed as percentage weight by volume (w/v) together with the calculated tonicity, proposed storage conditions, and predicted shelf life (Table 8). Specific observations on the sensitivity of the formulation to metals, hydrolysis, light, and oxygen also are included. This is normally printed for inclusion in a laboratory notebook, file, etc. If required, the formulation may be stored in a database for future reference.

As with the system developed for tablet formulations, this system contains extensive “Help” routines. No

Fig. 7 Screen images for the tablet formulation expert system as described by Rowe (20). (a) Shows user interface with windows for the formulation task tree, specification, formulation, and current task. Tasks are displayed in various formats—current task in highlighted or bold text, completed in italics, and future in standard text. (b) Shows the security of the system. The input of a password displays the user privileges.

Table 8 An example of a formulation of an intravenous injection for clinical trials in man as generated by the system described by Rowe et al.

<i>Drug properties (inputs)</i>		
Drug type		Acid
pK _a		4.5, 3.5

Chelating agent	Disodium edetate	0.02
	Water for injection to	100.00
<i>Predicted solution properties</i>		
pH	7.4	
Tonicity	Hypertonic (1.6)	
Storage temperature (°C)	25	
Atmosphere for filling	Nitrogen	
Shelf life (years)	>5	

(From Ref. 23.)

formulation optimization routines are included, although a routine to develop a placebo formulation to match the active formulation is included. The system is used to recommend parenteral formulations for a wide range of investigational drugs.

Work on expert systems in the specific domain of tablet film coating was initiated in April 1990, using a rule induction tool in order to develop a system for the identification and solution of defects in film-coated tablets. Although not strictly a formulation expert system, the developed system did contain knowledge whereby a given formulation known to cause defects could be modified to provide a solution. The completed system described by Rowe and Upjohn (24, 25) is a perfect illustration of fault diagnosis with a rule-based decision tree including both forward and backward chaining. Total development time was approximately 1 man-month using both documented knowledge (26) and expert assistance.

The system (Fig. 9) is divided into three parts: identification, solution, and information/references. In the first part, a question and answer routine is used to ascertain the correct identification of the defect. The decision tree used for this process is shown in Fig. 10.

At this point, the user is asked to confirm the decision by comparing the defect with a picture or photographs stored in the database. In the second part, the user is asked to enter all relevant process conditions and formulation details regarding the best way of solving the defect. This may be a change in the process conditions, as in the case of defects occurring with an already registered formulation, or a change in the formulation, as in the case of defects occurring at the formulation development stage. In the third part, the user is able to access data and knowledge regarding each defect. These are in the form of notes, photographs, and literature references connected by hypertext links.

In 1994, due to the successful implementation of both this system and that used to formulate tablets, it was decided to initiate work on a new system that would recommend film-coating formulations for the generated tablet formulations, combined with a reformulation routine based on the film defect diagnosis system (27). The structure of the new system is shown in Fig. 11. The knowledge for the system was acquired by interviewing two domain experts, one with extensive heuristic knowledge and the other with extensive research knowledge. The sequence is as follows: unital)

Fig. 8 Structure of the expert system developed by Rowe et al. (23) for the formulation of parenterals.

1. The user enters details of the tablet formulation (e.g., dose of active ingredient and all excipients) together with all tablet properties (e.g., diameter, thickness, strength, friability, color, shape, and the presence/ absence of intagliations).
2. The user enters specifications for the film coating formulation (i.e., immediate release/controlled release, enterosoluble, white or colored).
3. The system first checks that there are no inconsistencies between the input details and the required specification (e.g., tablets with high friabilities are extremely difficult to film coat). If positive, a warning is displayed.
4. The system calculates the surface area of the tablet and selects the required polymer at the recommended level to form a film of reasonable thickness.

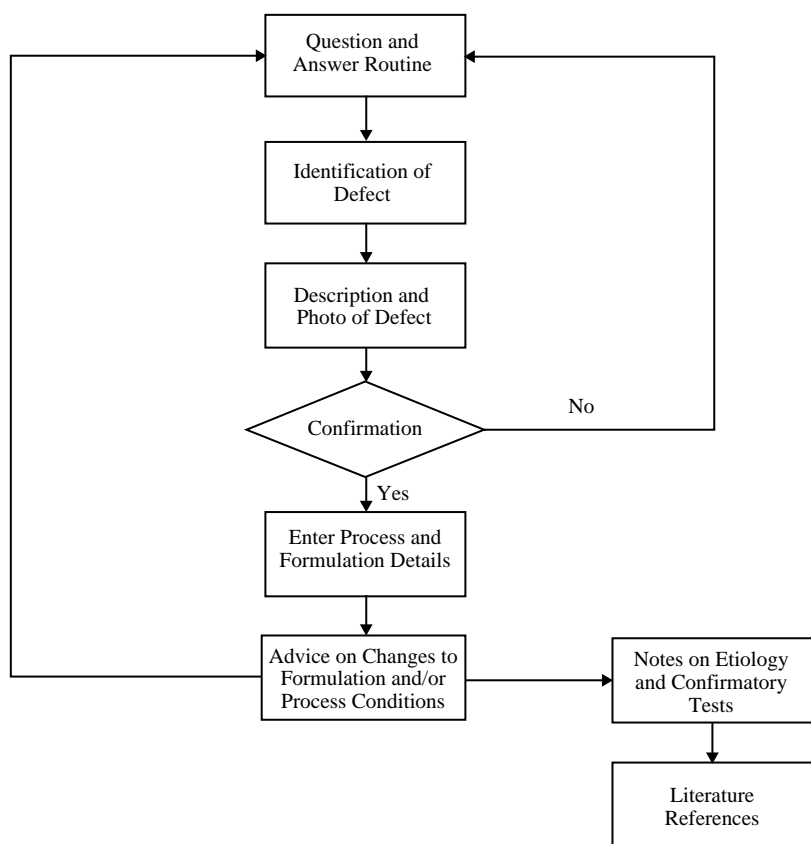

Fig. 9 Structure of the expert system for the identification and solution of film coating defects as described by Rowe and Upjohn (24, 25).

Table 9 An example of a formulation of a white film coating for a tablet of a model drug as generated by the system described by Rowe et al.

<i>Tablet properties (inputs)</i>		
Tablet core formulation	Drug A 50 mg	
Punch shape	Normal concave	
Weight (mg)	230	
Diameter (mm)	8.0	
Thickness (mm)	3.5	
Surface area (cm ²)	1.49	
<i>Formulation</i>	mg/tab	mg/cm ²
Polymer Hydroxypropyl methylcellulose (6 cps)	6.14	4.12
Plasticizer Polyethylene glycol (PEG 400)	1.23	0.82
Pigment Titanium dioxide (Anatase)	5.63	3.78
<i>Predicted film properties</i>		
Thickness (μm)	45	
Opacity (%)	94.9	
Crack velocity (ms ⁻¹)	5.71	

(From Ref. 27.)

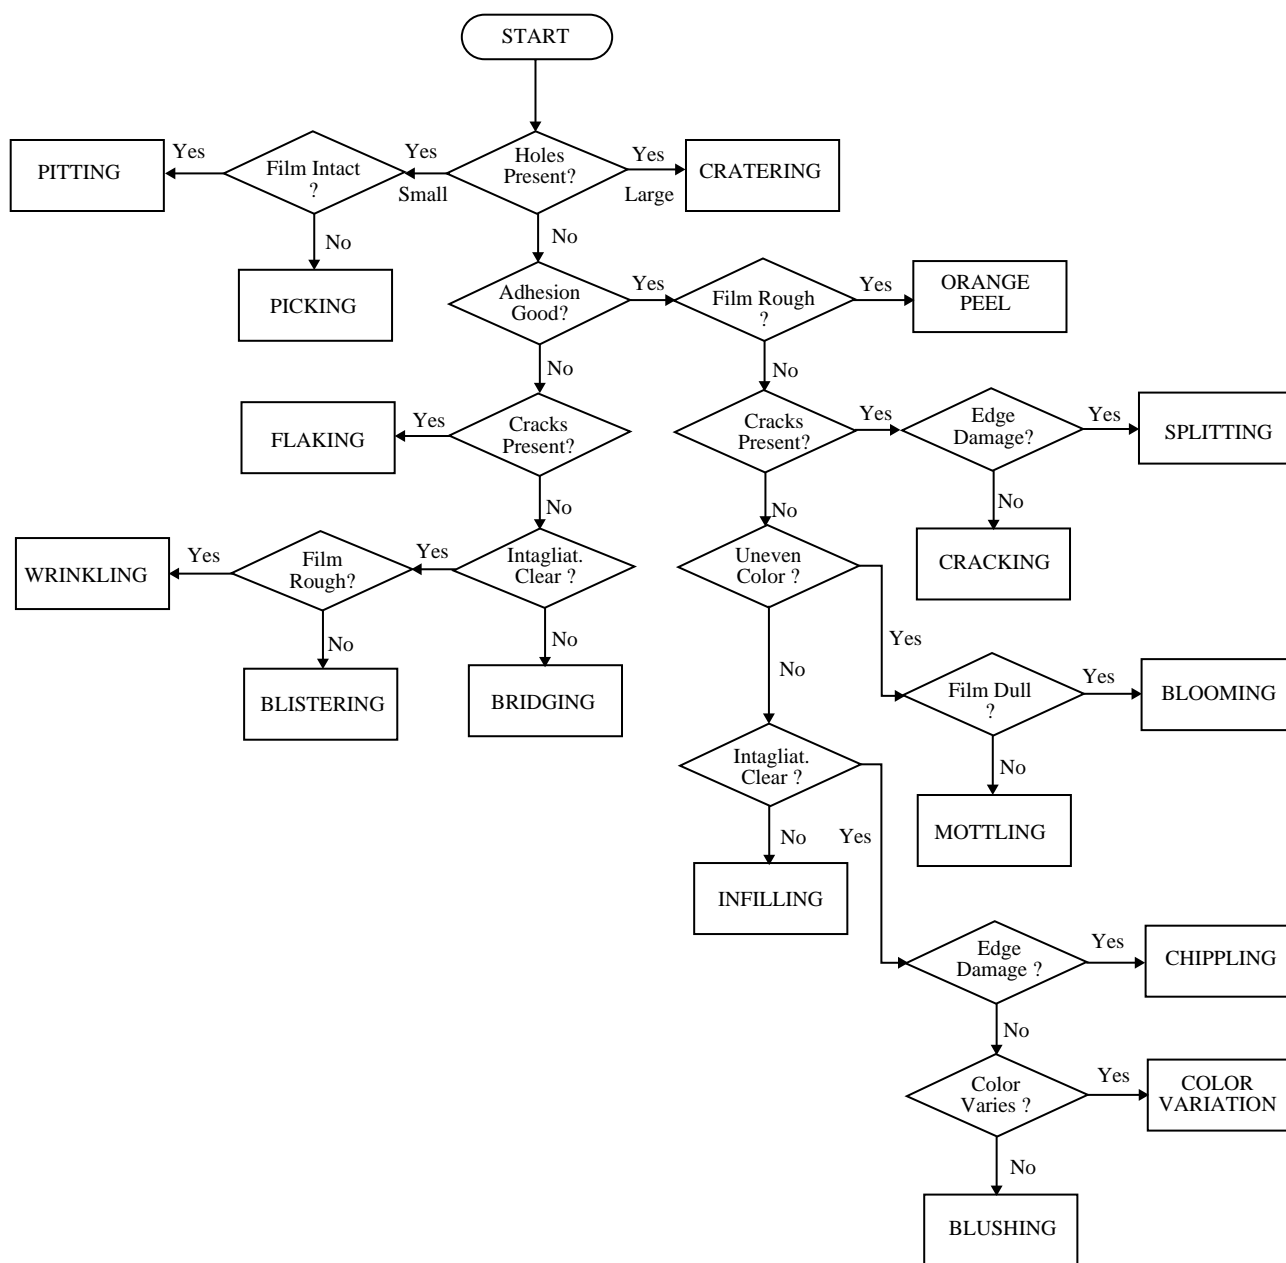

Fig. 10 A decision tree for the identification of film defects on film-coated tablets. (From Ref. 25).

5. The system selects a plasticizer and checks that there are no stability/compatibility problems. If positive, the user is asked to select an alternative plasticizer.
6. The system defines the target opacity of the film coating and decides if an opaque coating is required. The opacity is assessed by means of the contrast ratio defined as the ratio of the reflectance of the film when viewed with a black background to that viewed with a white background (the higher the value the more opaque the film) (28, 29). If positive and the

specification has been set as white, the system uses specifically developed algorithms (30, 31) to calculate if the target specification can be achieved within certain predefined formulation limits of the volume concentration of titanium dioxide and film thickness. If negative, the user is provided with a series of options to continue with the predefined limits, change the limits, or select a colored film coating.

7. The system selects the pigments to achieve the target specification and determines the amount of water

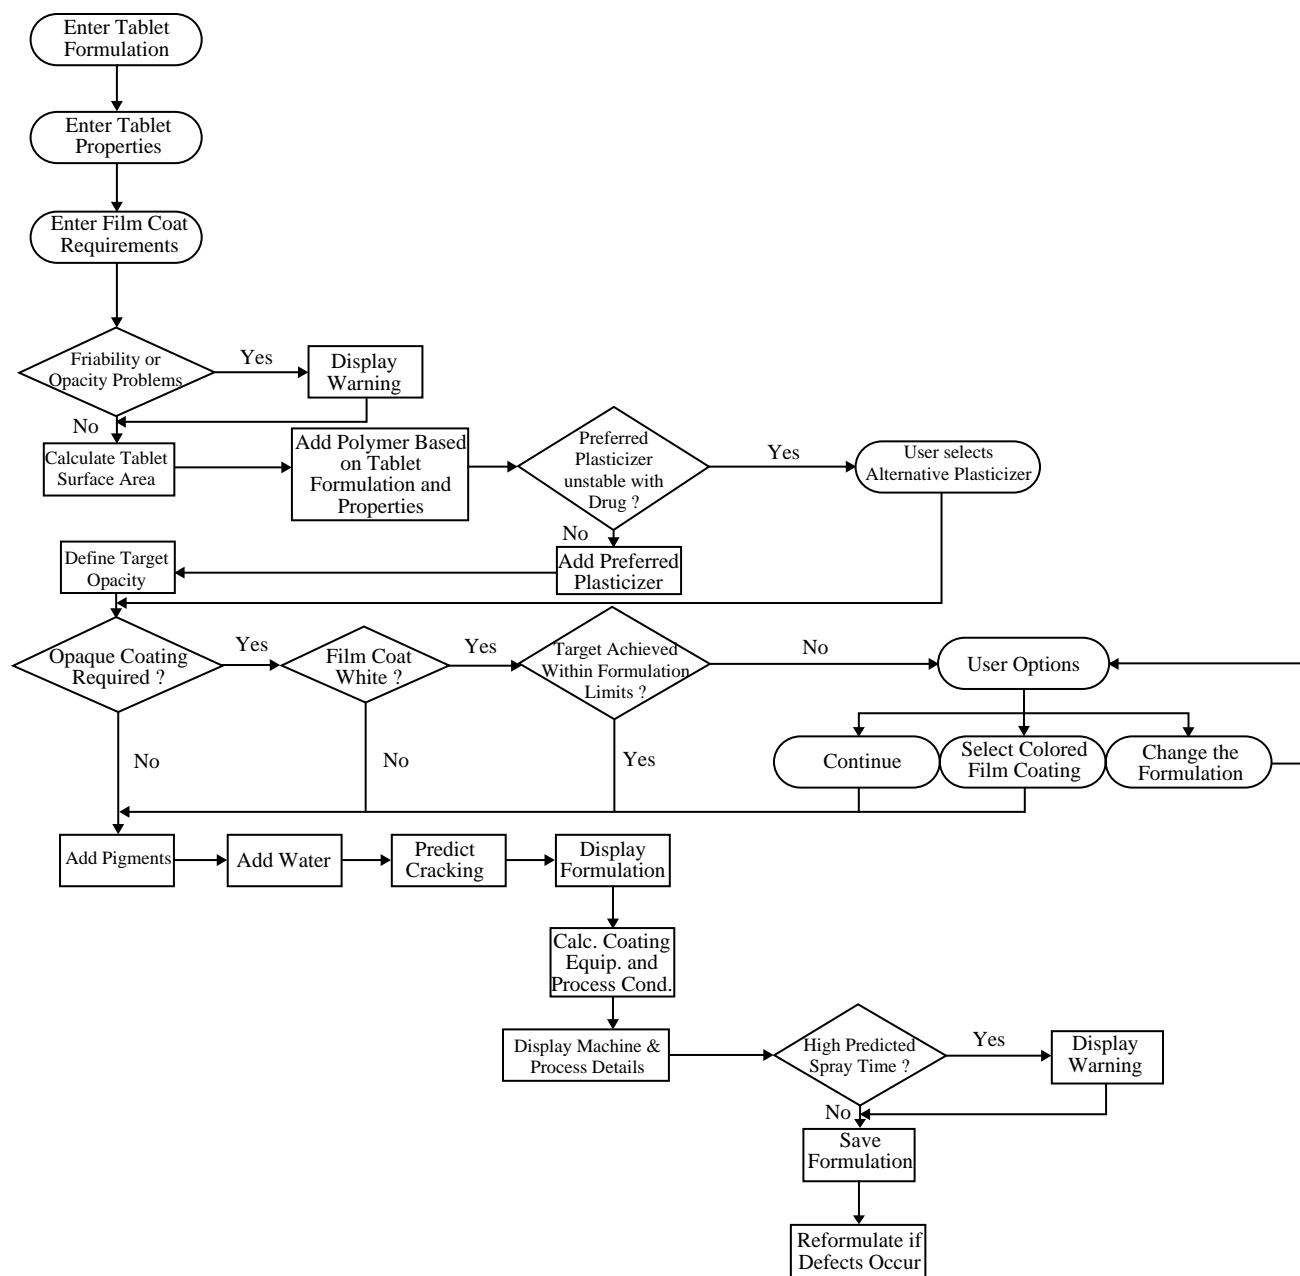

Fig. 11 Structure of the expert system developed by Rowe et al. (27) for the formulation of tablet film coatings.

(the system has been developed for aqueous film coating only).

8. The system accesses a simulation program written in C to predict the cracking propensity of the film formulation (32–34).
9. The recommended formulation is displayed (Table 9) and includes predicted film thickness, opacity, and cracking propensity. Standard machine settings and process details also are displayed with warnings

if the total spray time is judged to be excessive. This is normally printed for inclusion in a laboratory notebook or file. If required and in particular if reformulation is likely to be necessary, the data may be stored in a database for future reference.

10. If a reformulation is necessary due to the presence of defects after coating, then the system uses a modified form of the defect diagnosis system to recommend changes in the formulation and/or process conditions.

This system has proved successful in initial trials, especially in the formulation of opaque films for drugs that are either unstable to light or colored, producing mottled tablets. The calculations concerning the achievement of the target opacity within predefined limits have enabled formulators to make informed decisions regarding the use of white or colored film coatings. The system is now an integral part of the development strategy for film-coated tablets and now has a common database with the tablet formulation system.

BENEFITS

Expert systems have many benefits. These include the following:

1. *Knowledge protection and availability.* The existence of a coherent, durable knowledge base not affected by staff turnover (20). The developers of the University of London/Capsugel system have reported the benefit of being able to use knowledge from experts from many industrial companies in Europe, the United States, and Japan (14, 15). The developers of both the Cadila and the Sanofi systems have reported the benefit of the prompt availability of information and the rapid access to physical chemical data of both drugs and excipients, reducing the time spent searching the literature (9, 19).
2. *Consistency.* All systems generate robust formulations with increased certainty and consistency. This is seen as a distinct benefit where regulatory issues are important.
3. *Training aid.* All systems have been used to provide training for both novice and experienced formulators. The developers of the SOLTAN system have stated that experienced formulators use their expert systems to expose themselves to new raw material combinations with which they are not familiar. Bateman et al. (19) suggested the documentation used in the development of the Sanofi system be adapted to train novice formulators.
4. *Speed of development.* Reduction in the duration of the formulation process has been reported by many (8, 9, 20). Wood (8) reported that formulators who use SOLTAN can produce a formulation in 20 min that might otherwise have taken 2 days. Ramani et al. (9) reported a 35% reduction in the total time needed to develop a new tablet formulation.
5. *Cost savings.* Cost savings can be achieved not only by reducing the development time but also by the more effective use of materials, especially if material cost and controls are included in the system. Ramani et al. (9) reported that use of their system has been a benefit in planning the purchase and stocking of excipients.

The developers of SOLTAN reported that formulations generated by their system are cost effective not only for savings in raw material costs but also because fewer numbers of ingredients are used as compared to traditional formulations. Several users have also reported a decrease in the size of raw material inventories since their expert systems only use those materials specified in the database.

6. *Freeing experts.* The implementation of expert systems in product formulation has inevitably allowed expert formulators to devote more time to innovation (8, 20). The developers of the SOLTAN system reported that the time saved using their expert system typically releases about 30 days of formulating time per year per formulator. Of course, experienced formulators originally involved in training also will have more time to devote to innovation.
7. *Improved communication.* Rowe (20) reported that expert systems in his company have provided a common platform from which to discuss and manage changes in working practice and to identify those critical areas requiring research and/or rationalization. The developers of SOLTAN reported that use of their system has made them scrutinize the way in which they formulated products, highlighting shortfalls from the ideal. They also report that they have discovered previously unknown relationships between ingredients and properties in their products. The benefit of an expert system in promoting discussion also was reported by Bateman et al. (19).

Of all the systems in product formulation, only one has provided costings and undertaken a cost benefit analysis. The developers of SOLTAN estimated the overall cost of their system to be £10,400 for hardware and software, £6000 for consultancy, and £9000 for expert's time, making a total of £25,400. Annual cost savings in the region of £200,000 were reported, delivering a payback of approximately 3 months.

It is interesting to note that where expert systems have been implemented in product formulation, early skepticism among potential users has generally changed to a mood of enthusiastic participation. It is unlikely that expert systems will ever replace expert formulators, but as a decision support tool they are invaluable, delivering many measurable and intangible benefits.

CONCLUSION

Expert systems have been developed by a number of pharmaceutical companies and academic institutes in

order to cover the most common formulation types. Only those that have been mentioned in the open literature have been discussed, although it is generally known that SmithKline Beecham, Glaxo Wellcome, Eli Lilly, and Pfizer also have developed systems. It is possible that many more systems exist, but reticence with regard to publication abounds, and it is difficult to estimate exactly the number developed.

INTRODUCTION

The term pharmaceutical excipient or additive denotes compounds that are added to the finished drug product for a variety of reasons. Most often excipients are major components of the drug product, with the active drug molecule present in a small percentage. Excipients also have been referred to as inactive or inert ingredients to distinguish them from the active pharmaceutical ingredients. However, in many instances excipients may not be as inert as some scientists believe. Several countries have restrictions on the type or the amount of excipient that can be included in the formulation of parenteral drug products due to safety issues. For example, in Japan, amino mercuric chloride, or thimerosal use is prohibited, even though these excipients are present in several products in the United States.

As defined in the *European Pharmacopoeia* (EP) 1997 and the *British Pharmacopoeia* (BP) 1999, "Parenteral preparations are sterile preparations intended for administration by injection, infusion, or implantation into the human or animal body" (1, 2). However, for the purposes of this article, only sterile preparations for administration by injection or infusion into the human body will be surveyed. Injectable products require a unique formulation strategy. The formulated product has to be sterile, pyrogen free, and in the case of solutions, free of particulate matter. No coloring agent may be added solely for the purpose of coloring the parenteral preparation. Preferably, the formulation should be isotonic, and depending on the route of administration, certain excipients may not be allowed. For a given drug, the risk of an adverse event may be higher or the effects may be difficult to reverse if it is administered as an injection versus a nonparenteral route, since the injected drug bypasses natural defense barriers. The requirement for sterility demands that the excipient be able to withstand terminal sterilization or aseptic processing. These factors limit the choice of excipients available to the formulator.

Generally, a knowledge of which excipients have been deemed safe by the Food and Drug Administration (FDA) or are already present in a marketed product provides increased assurance to the formulator that these excipients will probably be safe for their new drug product. However, there is no guarantee that the new drug product will be safe as excipients are combined with other additives and/or with a new drug molecule, creating unforeseen potentiation or synergistic toxic effects. Regulatory bodies may view favorably an excipient previously approved in an injectable dosage form and will frequently require less safety data. A new additive in a formulated product will always require additional studies adding to the cost and timeline of product development.

In Japan, if the drug product contains an excipient with no precedence of use in that country, then the quality and safety attributes of the excipient must be evaluated by the Subcommittee on Pharmaceutical Excipients of the Central Pharmaceutical Affairs Council concurrently with the evaluation of the drug product application (3). Precedence of use means that the excipient has been used in a drug product in Japan, and will be administered via the same route and in a dose level equal to or greater than the excipient in question in the new application.

This chapter is a comprehensive review of the excipients included in the injectable products marketed in the United States, Europe, and Japan. A review of the literature indicates that only a few articles that specifically deal with the selection of parenteral excipients have been published (4–9). However, excipients included in other sterile dosage forms not administered parenterally, such as solutions for irrigation, ophthalmic or otic drops, and ointments, will not be covered.

Several sources of information were used to summarize the information compiled in this chapter (4–7, 10–14). Formulation information on the commercially available injectable products was entered in a worksheet. Tables presented in this chapter are condensed from this

worksheet. Each table is categorized based on the primary function of the excipient in the formulation. For example, citrates are classified as buffers and not as chelating agents, and ascorbates are categorized as antioxidants, although they can serve as buffers. This classification system minimizes redundancy and provides a reader-friendly format. The concentration of excipients is listed as percent weight by volume (w/v) or volume by volume (vol%). If the product was listed as lyophilized or powder, the percentages were derived based on the reconstitution volume commonly used. The tables list the range of concentration and examples of products containing the excipient, especially those that use an extremely low or high concentration.

TYPES OF EXCIPIENTS

Solvents and Cosolvents

Table 1 lists solvents and cosolvents used in parenteral products. Water for injection is the most common solvent but may be combined or substituted with a cosolvent to improve the solubility or stability of drugs (15, 16). The dielectric constant and solubility parameters are among the most common polarity indices used for solvent blending (17, 18). Ethanol and propylene glycol are used either

alone or in combination with other solvents in more than 50% of parenteral cosolvent systems. Surprisingly, propylene glycol is used more often than polyethylene glycols (PEGs) in spite of its higher myotoxicity and hemolyzing effects (19–22). The hemolytic potential of cosolvents is as follows (19):

Dimethyl acetamide < PGE400 < Ethanol
< Propylene glycol
< Dimethyloxide

It is possible that the presence of residual peroxide from the bleaching of PEG or the generation of peroxides in PEG may result in the degradation of the drug in the cosolvent system. It is important to use unbleached and/or peroxide-free PEGs in the formulation.

Oils such as safflower and soybean are used in total parenteral nutrition products, where they serve as a fat source and as carriers for fat-soluble vitamins. The *U.S. Pharmacopeia* (USP) requirement for injectable oils is as follows:

- A. Fixed oils (of vegetable origin)
- Saponification value (185–200)
 - Iodine number (79–128). (*The Japanese Pharmacopoeia* (JP) recommends value between 79–137.)

Table 1 Solvents and cosolvents

Excipient	Frequency	Range	Example
Almond oil	1	ND	Poison Ivy Extract (Parke Davis)
Benzyl benzoate	3	20–44.7% w/v	Delestrogen [®] 40 mg/ml (Bristol Myers) 44.7% w/v
Castor oil	1	ND	Delestrogen [®] 20 mg/ml (Bristol Myers) 44.7% w/v
Cottonseed oil	2	73.6–87.4% w/v	Depo-Testadiol [®] (Upjohn) 87.4% w/v
<i>N,N</i> -Dimethylacetamide	2	6–33% w/v	Busulfex [®] (Orphan Medical) 33%
Ethanol	26	0.6–100%	Prograf (Fujisawa) 80 vol%, Alprostadil (Bedford Lab) 100%
Glycerin (glycerol)	12	1.6–70% w/v	Multitest CMI [®] (Pasteur Merieux) 70% w/v
Peanut oil	1	ND	Bal in Oil [®] (Becton Dickinson)
Polyethylene glycol			
PEG	5	0.15–50%	Secobarbital sodium (Wyeth-Ayerst) 50%
PEG 300	3	50–65%	VePesid [®] (Bristol Myers) 65% w/v
PEG 400	3	18–67 vol%	Busulfex [®] (Orphan Medical) 67%
PEG 600	1	5% w/v	Persantine [®] (Dupont-Merck)
PEG 3350	5	0.3–3%	Depo-Medrol [®] (Upjohn) 2.95% w/v
Poppyseed oil	1	ND	Ethiodol [®] (Savage)
Propylene glycol	29	0.2–80%	Ativan [®] (Wyeth-Ayerst) 80%
Safflower oil	2	5–10%	Liposyn II [®] (Abbott) 10%
Sesame oil	6	100%	Solganal Inj. [®] (Schering)
Soybean oil	4	5–20% w/v	Intralipid [®] (Clintec) 20%
Vegetable oil	2	ND	Virilon IM Inj. [®] (Star Pharmaceuticals)

ND, No data available.

- Test for unsaponifiable matter
 - Test for free fatty acid
 - Solid paraffin test at 10°C
 - Acid value NMT 0.56 (*JP* only)
- B. Synthetic mono- and diglycerides of fatty acids (which are liquid and remain so when cooled to 10°C)
- Iodine number (<140)
 - Solid paraffin test at 10°C

The oils also are used to dissolve drugs with low aqueous solubility and provide a mechanism to slowly release drug over a long period of time. Deterioration of fixed oils, which leads to rancidity and production of free fatty acids, must be avoided in injectable products. Also the fixed oils or fatty acid esters must not contain mineral oil or paraffin which the body cannot metabolize.

Polymeric and Surface Active Compounds

Table 2 includes a broad category of excipients whose function in formulation could be as follows:

1. To impart viscosity or act as suspending agents such as carboxy methyl cellulose, sodium carboxy methyl

cellulose, acacia, Povidone, hydrolyzed gelatin, and sorbitol.

2. To act as solubilizing, wetting, or emulsifying agents such as Cremophor EL, sodium desoxycholate, Polysorbate 20 or 80, PEG 40 castor oil, PEG 60 castor oil, sodium dodecyl sulfate, lecithin, or egg yolk phospholipid.
3. To form gels such as when aluminum monostearate is added to fixed oil to form a viscous or gel-like suspension medium.

Polysorbate 80 is the most common and versatile solubilizing, wetting and emulsifying agent. Again, one must be concerned about the level of residual peroxides present in polysorbates and protecting them from air to prevent further oxidation (23). Polysorbate 80 is polyoxyethylene sorbitan ester of oleic acid (unsaturated fatty acid) while polyoxyethylene Polysorbate 20 is sorbitan ester of lauric acid (saturated fatty acid). Thus, stability differences could occur in the drug product formulated with Polysorbate 80 versus Polysorbate 20. One example is Neupogen[®] which when exposed to a high concentration of Polysorbate 20 exhibited substantially less oxidation than when exposed to a similar concentration of Polysorbate 80 (24).

Table 2 Solubilizing, wetting, suspending, emulsifying, or thickening agents

Excipient	Frequency	Range	Example
Acacia	2	7%	Tuberculin Old Test [®] (Lederle) 7%
Aluminum monostearate	1	2%	Solganal Inj. [®] (Schering) 2%
Carboxy methyl cellulose	4	0.50–0.55%	Bicillin [®] (Wyeth-Ayerst) 0.55%
Carboxy methyl cellulose, sodium	19	0.15–3.0%	Nutropin Depot [®] (Genentech) 3%
Cremophor EL ^a	3	50–65% w/v	Sandimmune [®] (Sandoz) 65% w/v
Desoxycholate sodium	1	0.4% w/v	Fungizone [®] (Bristol Myers) 0.41% w/v
Egg yolk phospholipid	3	1.2%	Intralipid [®] (Clintec) 1.2%
Gelatin, Hydrolyzed	1	16% w/v	Cortone [®] (Merck) 16% w/v
Lecithin	8	0.4–1.2% w/v	Diprivan [®] (Zeneca) 1.2% w/v
Pluronic F-68	1	—	Fluosol [®] (Alpha Therapeutics)
Polyoxyethylated fatty acid	2	7–12% w/v	AquaMephyton [®] (Merck) 7% w/v Aquasol A parenteral [®] (Astra) 12%
Polysorbate 80 (Tween 80)	48	0.004–100%	Taxoterer [®] (Aventis) 100%
Polysorbate 20 (Tween 20)	9	0.01–0.4%	Calcijex [®] (Abbott) 0.4% w/v
PEG 40 castor oil ^b	1	11.5 vol%	Monistat [®] (Janssen) 11.5 vol%
PEG 60 castor oil ^c	1	20% w/v	Prograf [®] (Fujisawa) 20% w/v
Povidone (Polyvinyl pyrrolidone)	7	0.5–0.6% w/v	Bicillin [®] (Wyeth-Ayerst) 0.6% w/v
Sodium dodecyl sulfate (Na lauryl sulfate)	1	0.018% w/v	Proleukin [®] (Cetus) 0.018% w/v
Sorbitol	3	25–50%	Aristrospan [®] (Fujisawa) 50 vol%

^aCremophor EL, Etocas 35, polyethoxylated castor oil, polyoxyethylene 35 castor oil.

^bPEG 40 castor oil, polyoxyl 40 castor oil, castor oil POE-40, Croduret 40, polyoxyethylene 40 castor oil, Protachem CA-40.

^cPEG 60 hydrogenated castor oil, Cremophor RH 60, hydrogenated castor oil POE-60, Protachem CAH-60.

Table 3 Chelating agents

Excipient	Frequency	Range	Example
Calcium disodium EDTA ^a	9	0.01–0.1%	Wydase [®] (Wyeth-Ayerst) 0.1% w/v
Disodium EDTA	38	0.01–0.11%	Calcijex [®] (Abbott) 0.11% w/v
Sodium EDTA	1	0.20%	Folvite [®] (Lederle) 0.20%
DTPA ^b	1	0.04%	Magnevist [®] (Berlex) 0.04%

^aEDTA = Ethylenediaminetetraacetic acid.^bDTPA = Diethylenetriaminepentaacetic acid; pentetic acid.

Chelating Agents

Only a limited number of chelating agents are used in parenteral products (Table 3). They serve to complex heavy metals and therefore can improve the efficacy of antioxidants or preservatives. Citric acid, tartaric acid and some amino acids also can act as chelating agents. There have been some misunderstandings concerning the use of EDTA (as calcium salt) as an approved injectable product in Japan. Currently in Japan, some drug products that contain calcium disodium EDTA are on the market and this excipient is also listed as an official excipient (see Table 11). An advantage of calcium EDTA over tetrasodium salt is that calcium EDTA does not contribute sodium and does not chelate as much calcium from the blood.

A complexing agent should not be used in metallo-protein formulations, where the protein subunits are held

by the metal (25). The EDTA, in rare instances, can increase the oxidation rate due to binding of the EDTA–metal complex to protein, resulting in site-specific generation of radicals (26).

Antioxidants

Antioxidants are used to prevent the oxidation of active substances and excipients in the finished product. There are three main types of antioxidants:

1. *True antioxidants*: They act by a chain-termination mechanism by reacting with free radicals, e.g., butylated hydroxytoluene.
2. *Reducing agents*: They have a lower redox potential than the drug and get preferentially oxidized, e.g.,

Table 4 Antioxidants and reducing agents

Excipient	Frequency	Range	Example
Acetone sodium bisulfite	4	0.2–0.4% w/v	Novocaine [®] (Sanofi-Winthrop) 0.4% w/v
Ascorbate (sodium/acid)	8	0.1–4.8% w/v	Vibramycin [®] (Pfizer) 4.8% w/v
Bisulfite sodium	31	0.02–0.66% w/v	Amikin [®] (Bristol Myers) 0.66% w/v
Butylated hydroxy anisole (BHA)	3	0.00028–0.03% w/v	Aquasol A [®] (Astra) 0.03% w/v
Butylated hydroxy toluene (BHT)	3	0.00116–0.03% w/v	Aquasol A [®] (Astra) 0.03% w/v
Cystein/Cysteinate HCl	3	0.07–1.3% w/v	Acthrel [®] (Ferring) 1.3% w/v
Dithionite sodium (Na hydrosulfite, Na sulfoxylate)	1	0.10%	Numorphan [®] (Endo Lab) 0.10%
Gentisic acid	1	0.02% w/v	OctreoScan [®] (Mallinckrodt) 0.02% w/v
Gentisic acid ethanolamine	1	2%	M.V.I. 12 [®] (Astra) 2%
Glutamate monosodium	2	0.1% w/v	Varivax [®] (Merck) 0.1% w/v
Formaldehyde sulfoxylate sodium	9	0.02–0.5% w/v	Terramycin solution (Pfizer) 0.5% w/v
Metabisulfite potassium	1	0.10%	Vasoxyl [®] (Glaxo-Wellcome) 0.10%
Metabisulfite sodium	32	0.02–1% w/v	Intropin [®] (DuPont) 1% w/v
Monothioglycerol (Thioglycerol)	6	0.1–1%	Terramycin solution (Pfizer) 1%
Propyl gallate	2	0.02%	Navane [®] (Pfizer) 0.02%
Sulfite sodium	7	0.05–0.2% w/v	Enlon [®] (Ohmeda) 0.2% w/v
Tocopherol alpha	1	0.005% w/v	AmBisome [®] (Fujisawa) 0.005%
Thioglycolate sodium	1	0.66% w/v	Sus-Phrine [®] (Forest) 0.66% w/v

ascorbic acid. Thus, they can be consumed during the shelf-life of the product.

3. *Antioxidant synergists*: These enhance the effect of antioxidants, e.g., EDTA.

Table 4 summarizes the antioxidants, their frequency of use, concentration range, and examples of products containing them. Sulfite, bisulfite, and metabisulfite constitute the majority of antioxidants used in parenteral products despite several reports of incompatibility and toxicity (27, 28). Butylated hydroxy anisole, butylated hydroxy toluene, alpha tocopherol, and propyl gallate are primarily used in semi/nonaqueous vehicles because of their low aqueous solubility (29). Ascorbic acid/sodium ascorbate may serve as an antioxidant, buffer and chelating agent in the same formulation. Some amino acids such as cysteine also function as effective antioxidants.

The Committee for Proprietary Medicinal Products (CPMP) guideline calls for a full explanation and justification for including antioxidants in the formulation (30). It further states that antioxidants should only be included in a formulation if it has been proven that their use cannot be avoided. Thus, it is imperative to first try inert gas (nitrogen or argon) in the headspace to prevent oxidation. If the antioxidant has to be included, its concentration must be justified in terms of efficacy and safety. Antioxidants such as sulfites and metabisulfites are especially undesirable.

Some antioxidants possess antimicrobial properties, such as propyl gallate and butylated hydroxy anisole, which are somewhat effective against bacteria. Butylated hydroxy toluene has demonstrated some antiviral activity. Compatibility of antioxidants with the drug, packaging system and the body should be studied carefully. For example, tocopherols may be absorbed onto plastics;

ascorbic acid is incompatible with alkalis, heavy metals, and oxidizing materials such as phenylephrine, and sodium nitrite; and propyl gallate forms complexes with metal ions such as sodium, potassium and iron.

Preservatives

Benzyl alcohol is the most common antimicrobial preservative present in parenteral formulations (Table 5). This observation is consistent with other surveys (6, 31). Parabens are the second most common preservatives. Surprisingly, thimerosal is also common, especially in vaccines, even though some individuals are sensitive to mercurics. Several preservatives can volatilize easily (such as benzyl alcohol, and phenol) and, therefore, should not be used for lyophilized dosage form. Chlorocresol is purported to be a good preservative for parenterals, but our survey did not find any examples of commercial products containing chlorocresol. The British Pharmaceutical Codex and Martindale list chlorocresol as a preservative to be used in multidose aqueous injections at concentrations of 0.1% but no examples of injectable products have been provided (32, 33).

Antimicrobial preservatives are allowed in multidose injections to prevent growth of microorganisms that may accidentally enter the container during withdrawal of the dose. However, they are discouraged from being used in single-dose injections in the United States while the EP and BP allow aqueous preparations, that are manufactured using aseptic techniques, to contain suitable preservatives. It should be emphasized that preservatives should never be used as a substitute for inadequate good manufacturing practices (GMP). BP and EP prohibit antimicrobials from single-dose

Table 5 Antimicrobial preservatives

Excipient	Frequency	Range	Example
Benzalkonium chloride	1	0.02% w/v	Celestone Soluspan® (Schering) 0.02% w/v
Benzethonium chloride	4	0.01%	Benadryl® (Parke-Davis) 0.01% w/v
Benzyl alcohol	85	0.75–10%	Progesterone (United Res) 10%
Chlorbutanol	18	0.25–0.5%	Codine phosphate (Wyeth-Ayerst) 0.5%
<i>m</i> -Cresol	5	0.1–0.35%	Humalog® (Lilly) 0.35%
Myristyl gamma-picolinium chloride	2	0.0195–0.169% w/v	Depo-Provera® (Pharmacia-Upjohn) 0.169% w/v
Paraben methyl	52	0.05–0.18%	Inapsine® (Janssen) 0.18% w/v
Paraben propyl	44	0.01–0.1%	Xylocaine w/ Epinephrine (Astra) 0.1% w/v
Phenol	50	0.2–0.5%	Calcimar® (Rhone-Poulanc) 0.5% w/v
2-Phenoxyethanol	4	0.50%	Havrix® (SmithKline Beecham) 0.50% w/v
Phenyl mercuric nitrate	3	0.001%	Antivenin® (Wyeth-Ayerst) 0.001%
Thimerosal	48	0.003–0.012%	Atgam® (Pharmacia-Upjohn) 0.01%

Table 6 Maximum permissible amount of preservatives and antioxidants

Excipient	Maximum limit in USP
Mercurial compounds	0.01%
Cationic surfactants	0.01%
Chlorobutanol	0.50%
Cresol	0.50%
Phenol	0.50%
Sulfur dioxide or an equivalent amount of the sulfite, bisulfite, or metabisulfite of potassium or sodium	0.20%

injections where the dose volume is greater than 15 mL or if the drug product is to be injected via intracisternal, or any route which gives access to the cerebrospinal fluid (CSF). Toxicity is the primary reason for minimizing the use of antimicrobial preservatives. For example, many individuals are allergic to mercury preservatives while benzyl alcohol is contraindicated in children under the age of 2. USP has also placed some restrictions on the maximum concentration of preservatives allowed in the formulation to address toxicity and allergic reactions (Table 6). The World Health Organization (WHO) has set an estimated total acceptable daily intake for sorbate (as acid, calcium, potassium and sodium salts) as not more than 25 mg/kg body weight. The efficacy of the preservative should be assessed during product development using Antimicrobial Preservative Effectiveness Testing (PET) (34–36). Thus, an aqueous-preserved parenteral product can be used up to a maximum of 28 days after the container has been opened (37). Obviously, 28 days has to be justified by performing PET on the finished product in the final package. On the other hand, unpreserved products preferably should be used immediately following opening, reconstitution, or dilution.

Buffers

Buffers are added to a formulation to adjust the pH in order to optimize solubility and stability. For parenteral preparations, the pH of the product should be close to physiologic pH. The selection of buffer concentration (ionic strength) and buffer species is important. For example, 5–15 mM of citrate buffers are used in the formulation but increasing buffer concentration to >50 mM will result in excessive pain on subcutaneous injection and toxic effects due to the chelation of calcium in the blood.

Buffers have maximum buffer capacities near their pK_a . For products that may be subjected to excessive temperature fluctuations during processing (such as sterilization or lyophilization), it is important to select buffers with a small $\Delta pK_a/^\circ\text{C}$. Thus, Tris, whose $\Delta pK_a/^\circ\text{C}$ is large ($-0.028/^\circ\text{C}$), the pH of buffer made at 25°C will change from 7.1 to 5.0 at 100°C . This may dramatically alter the stability or solubility of the drug. Similarly, the best buffers for a lyophilized product may be those that show the least pH change upon cooling, that do not crystallize out, and that can remain in the amorphous state protecting the drug. For example, replacing succinate with glycolate buffer improves the stability of lyophilized interferon- γ (38). During the lyophilization of mannitol that contains succinate buffer at pH 5, monosodium succinate crystallizes, reducing the pH and resulting in the unfolding of interferon- γ . This pH shift is not seen with glycolate buffer.

Table 7 lists buffers and chemicals used to adjust the pH of formulations and the product pH range. Phosphate, citrate, and acetate are the most common buffers used in parenteral products. Mono- and diethanolamines are added to adjust pH and form corresponding salts. Hydrogen bromide, sulfuric acid, benzene sulfonic acid, and methane sulfonic acids are added to drugs which are salts of bromide (Scopolamine HBr, Hyoscine HBr), sulfate (Nebcin, Tobramycin sulfate), besylate (Tracrium Injection, Atracurium besylate) or mesylate (DHE 45 Injection, Dihydroergotamine mesylate). Glucono delta lactone is used to adjust the pH of Quinidine gluconate. Benzoate buffer, at a concentration of 5%, is used in Valium Injection. Citrates are a common buffer that can have a dual role as chelating agents. The amino acids lysine and glycine, function as buffers and stabilize proteins and peptide formulations. These amino acids are also used as lyo-additives and may prevent cold denaturation. Lactate and tartrate are occasionally used as buffer systems. Acetates are good buffers at low pH, but they are not generally used for lyophilization because of potential sublimation of acetates.

Bulking Agents, Protectants, and Tonicity Adjusters

Table 8 lists additives that are used to modify osmolality, and as bulking or lyo/cryoprotective agents. Dextrose and sodium chloride are used to adjust tonicity in the majority of formulations. Some amino acids such as glycine, alanine, histidine, imidazole, arginine, asparagine, and aspartic acid are used as bulking agents for lyophilization and also can serve as stabilizers, and/or as buffers.

Table 7 Buffers and pH-adjusting agents

Excipient	pH Range	Example
Acetate		
Sodium	3.7–4.3	Syntocinon [®] (Novartis)
Acetic acid	3.7–4.3	Syntocinon [®] (Novartis)
Glacial acetic acid	3.5–5.5	Brevibloc [®] (Ohmeda)
Ammonium	6.8–7.8	Bumex Injection [®] (Roche)
Ammonium sulfate	—	Innovar [®] (Astra)
Ammonium hydroxide	—	Triostat [®] (Jones Medical)
Arginine	7.0–7.4	Retavase [®] (Boehringer)
Aspartic acid	5.7–6.4	Pepcid [®] (Merck)
Benzene sulfonic acid	3.25–3.65	Nimbex [®] (Glaxo Wellcome)
Benzoate Sodium/acid	6.2–6.9	Valium [®] (Roche)
Bicarbonate	5.5–11.0	Cenolate [®] (Abbott)
Boric acid/sodium		Comvax [®] (Merck)
Carbonate, sodium	5.0–11.0	Hyperab [®] (Bayer)
Citrate		
Acid	3.0–5.5	DTIC-Dome [®] (Bayer)
Sodium	3.5–6.5	Amikin [®] (Bristol Myers)
Disodium	—	Cerezyme [®] (Genzyme)
Trisodium	—	Cerezyme [®] (Genzyme)
Diethanolamine	9.5–10.5	Bactim IV [®] (Roche)
Glucono delta lactone	5.5–7.0	Quinidine Gluconate (Lilly)
Glycine/glycine HCl	6.4–7.2	Hep-B Gammagee [®] (Merck)
Histidine/histidine HCl	6.5	Doxil [®] (Sequus)
Hydrochloric acid	6.0–7.6	Amicar [®] (Immunex)
Hydrobromic acid	3.5–6.5	Scopolamine (UDL)
Lactate sodium/Acid	2.7–5.7	Innovar [®] (Janssen)
Lysine (L)	—	Eminase [®] (Roberts)
Maleic acid	3.0–5.0	Librium [®] (Roche)
Meglumine	6.5–8.0	Magnevist [®] (Berlex)
Methanesulfonic acid	3.2–4.0	DHE-45 [®] (Novartis)
Monoethanolamine	8.0–9.0	Terramycin (Pfizer)
Phosphate		
Acid	6.5–8.5	Saizen [®] (Serono Labs)
Monobasic potassium	6.7–7.3	Zantac [®] (Glaxo-Wellcome)
Monobasic sodium ^a	6.0–8.0	Pregnyl [®] (Organon)
Dibasic sodium ^b	6.7–7.8	Zantac [®] (Glaxo-Wellcome)
Tribasic sodium	—	Synthroid [®] (Knoll)
Sodium hydroxide	Broad range	Optiray [®] (Mallinckrodt)
Succinate sodium/Disodium	5.0–6.0	AmBisome [®] (Fujisawa)
Sulfuric acid	3.0–6.5	Nebcin [®] (Lilly)
Tartrate sodium/acid	2.7–6.2	Methergine [®] (Novartis)
Tromethamine	6.0–7.5	Optiray [®] (Mallinckrodt)

^aSodium biphosphate, sodium dihydrogen phosphate, or Na dihydrogen orthophosphate.^bSodium phosphate, disodium hydrogen phosphate.

Monosaccharides (dextrose, glucose, maltose, lactose), disaccharides (sucrose, trehalose), polyhydric alcohols (inositol, mannitol, sorbitol), glycols (PEG 3350), Povidone (polyvinylpyrrolidone, PVP) and proteins (albumin, gelatin) are commonly used as lyo-additives.

Hydroxyethyl starch (hetastarch) and pentastarch, which are currently used as plasma expanders in commercial injectable products such as Hespan and Pentaspan, also are being evaluated as protectants during freeze-drying of proteins.

Table 8 Bulking agents, protectants, and tonicity adjusters

Excipient	Example
Alanine	Thrombate III [®] (Bayer)
Albumin	Bioclate [®] (Arco)
Albumin (human)	Botox [®] (Allergan)
Amino acids	Havrix [®] (Smith Kline Beecham)
Arginine (L)	Activase [®] (Genentech)
Asparagine	Tice BCG [®] (Organon)
Aspartic acid (L)	Pepcid [®] (Merck)
Calcium chloride	Phenergan [®] (Wyeth-Ayerst)
Cyclodextrin-alpha	Edex [®] (Schwartz)
Cyclodextrin-gamma	Cardiotec [®] (Squibb)
Dextran 40	Etopophos [®] (Bristol Myers)
Dextrose	Betaseron [®] (Berlex)
Gelatin (cross-linked)	Kabikinase [®] (Pharmacia-Upjohn)
Gelatin (hydrolyzed)	Acthar [®] (Rhone-Poulanc Rorer)
Lactic & glycolic acid copolymers	Lupron Depot [®] (TAP)
Glucose	Iveegam [®] (Immuno-US)
Glycerine	Tice BCG [®] (Organon)
Glycine	Atgam [®] (Pharmacia-Upjohn)
Histidine	Antihemophilic Factor, human (Am. Red Cross)
Imidazole	Helixate [®] (Armour)
Inositol	OctreoScan [®] (Mallinckrodt)
Lactose	Caverject [®] (Pharmacia-Upjohn)
Magnesium chloride	Terramycin Solution (Pfizer)
Magnesium sulfate	Tice BCG [®] (Organon)
Maltose	Gamimune N [®] (Bayer)
Mannitol	Elspar [®] (Merck)
Polyethylene glycol 3350	Bioclate [®] (Arco)
Polylactic acid	Lupron Depot [®] (TAP)
Polysorbate 80	Helixate [®] (Armour)
Potassium chloride	Varivax [®] (Merck)
Povidone	Alkeran [®] (Glaxo-Wellcome)
Sodium chloride	WinRho SD [®] (Univax)
Sodium cholesteryl sulfate	Amphotec [®] (Sequus)
Sodium succinate	Actimmune [®] (Genentech)
Sodium sulfate	Depo-Provera [®] (Pharmacia-Upjohn)
Sorbitol	Panhematin [®] (Abbott)
Sucrose	Prolastin [®] (Bayer)
Trehalose (alpha, alpha)	Herceptin [®] (Genentech)

PVP has been used in injectable products as a solubilizing agent, a protectant and as a bulking agent. Only pyrogen-free grade, with low molecular weight (*K* value less than 18) should be used in parenteral products to allow for rapid renal elimination. PVP not only solubilizes drugs such as rifampicin, but it also can reduce the local toxicity as seen in oxytetracycline injection.

Many proteins can be stabilized in the lyophilized state if the stabilizer and protein do not phase separate during freezing or the stabilizer does not crystallize out.

In the case of Neupogen[®] (GCSF), the original formulation was modified by replacing mannitol with sorbitol to prevent the loss of activity of liquid formulation in case of accidental freezing (24). Mannitol crystallizes if the solution freezes while sorbitol remains in an amorphous state protecting GCSF. Similarly, it is useful that the drug remains dispersed in the stabilizer upon freezing of the solution. Thus, Cefoxitin, a cephalosporin, is more stable when freeze-dried with sucrose than with trehalose, although the glass transition temperature and structural relaxation time is much

greater for trehalose than sucrose (39). FTIR data indicated that the trehalose–cefoxitin system phase separated into two nearly pure components, resulting in no protection (stability). Similarly, dextran was not found to be as useful a cryoprotectant for protein as sucrose because dextran and protein underwent phase segregation as the solution started to freeze. The mechanism of cryoprotection in the solution has been explained by the preferential exclusion hypothesis (40).

Trehalose is a nonreducing disaccharide composed of two D-glucose monomers. It is found in several animals that can withstand dehydration and therefore was suggested as a stabilizer of drugs that undergo denaturation during spray or freeze-drying (41). Herceptin® (Trastuzumab) is a recombinant DNA-derived monoclonal antibody (MAb) that is used for treating metastatic breast cancer. The MAb has been stabilized in the lyophilized formulation using α,α -trehalose dihydrate. Trehalose has also been used as a cryoprotectant to prevent liposomal aggregation and leakage. In the dried state, carbohydrates such as trehalose, and inositol, exert their protective effect by acting as a water substitute (42).

Additives may have to be included in the formulation to adjust the specific gravity. This is important for drugs that upon administration may come in contact with CSF. CSF has a specific gravity of 1.0059 at 37°C. Solutions that have the same specific gravity as that of CSF are termed isobaric, while those solutions that have specific gravity greater than that of CSF are called hyperbaric. Upon administration of a hyperbaric solution in the spinal cord, the injected solution will settle and will affect spinal nerves at the end of the spinal cord. For example, Dibucaine hydrochloride solution (Nupercaine® 1:200) is isobaric, while Nupercaine 1:500 is hypobaric (specific gravity of 1.0036 at 37°C). Nupercaine heavy solution is made hyperbaric by addition of 5% dextrose solution, and this solution will block (anesthetize) the lower spinal nerves as it settles in the spinal cord.

Special Additives

Special additives serve special functions in pharmaceutical formulations (Table 9). The following is a summary of special additives along with their intended use:

1. Calcium gluconate injection (American Regent) is a saturated solution of 10% w/v. Calcium D-saccharate tetrahydrate 0.46% w/v is added to prevent crystallization during temperature fluctuations.
2. Cipro IV® (Ciprofloxacin, Bayer) contains lactic acid as a solubilizing agent for the antibiotic.

3. Premarin Injection® (Conjugated Estrogens, Wyeth-Ayerst Labs) is a lyophilized product that contains simethicone to prevent the formation of foam during reconstitution.
4. Dexamethasone acetate (Dalalone DP, Forest, Decadron-LA, Merck) and Dexamethasone sodium phosphate (Merck) are available as a suspension or a solution. These dexamethasone formulations contain creatine or creatinine as additives.
5. Adriamycin RDF® (Doxorubicin hydrochloride, Pharmacia-Upjohn) contains methyl paraben, 0.2 mg/mL to increase dissolution (43).
6. Ergotrate maleate (Ergonovine maleate, Lilly) contains 0.1% ethyl lactate as a solubilizing agent.
7. Estradurin Injection® (Polyestradiol phosphate, Wyeth-Ayerst Labs) uses Niacinamide (12.5 mg/ml) as a solubilizing agent. Hydeltasol® also contains niacinamide. The concept of hydrotropic agents to increase water solubility has been tried on several compounds, including proteins (44, 45).
8. Aluminum, in the form of aluminum hydroxide, aluminum phosphate or aluminum potassium sulfate, is used as adjuvant in various vaccine formulations to elicit an increased immunogenic response.
9. Lupron Depot Injection® is lyophilized microspheres of gelatin and glycolic–lactic acid for intramuscular (IM) injection. Nutropin Depot consists of polylactate–glycolate microspheres.
10. Gamma cyclodextrin is used as a stabilizer in Cardiotec® at a concentration of 50 mg/mL.
11. Alprostadil (Edex®, Schwartz) is a lyophilized product of Prostaglandin E₁ in α -cyclodextrin inclusion complex. The complex has better stability and aqueous solubility than the drug itself.
12. Itraconazole (Sporanox®, Janssen) is solubilized as a molecular inclusion complex using hydroxypropyl- β -cyclodextrin.
13. Sodium caprylate (sodium octoate) has antifungal properties, but it is also used to improve the stability of albumin solution against the effects of heat. Albumin solution can be pasteurized by heating at 60°C for 10 h in the presence of sodium caprylate. Acetyl tryptophanate sodium is also added to albumin formulations.
14. Meglumine (*N*-methylglucamine) is used to form in situ salt. For example, diatrizoic acid, an X-ray contrast agent, is more stable when autoclaved as meglumine salt than as sodium salt (46). Meglumine is also added to Magnevist®, a magnetic resonance contrast agent.
15. Tri-*n*-butyl phosphate is present as an excipient in human immune globulin solution (Venoglobulin®). Its exact function in the formulation is not known, but it may serve as a scavenging agent.

Table 9 Special additives

Excipient	Example
Acetyl tryptophanate	Human Albumin (American Red Cross)
Aluminum hydroxide	Recombivax HB [®] (Merck)
Aluminum phosphate	Tetanus Toxoid Adsorbed (Wyeth-Ayerst)
Aluminum potassium sulfate	TD Adsorbed Adult (Pasteur Merieux)
ϵ -Aminocaproic acid	Eminase [®] (Roberts)
Calcium D-saccharate	Calcium Gluconate (American Regent)
Caprylate sodium	Human Albumin (American Red Cross)
8-Chlorotheophylline	Dimenhydrinate [®] (Steris)
Creatine	Dalalone DP [®] (Forest)
Creatinine	Decadron [®] (Merck)
Cholesterol	Doxil [®] (Sequus)
Cholesteryl sulfate sodium	Amphotec [®] (Sequus)
Alpha-cyclodextrin	Edex [®] (Schwartz)
Gamma-cyclodextrin	Cardiotec [®] (Squibb)
Hydroxypropyl beta cyclodextrin	Sporanox [®] (Janssen)
Distearyl Phosphatidylcholine	DaunoXome [®] (Nexstar)
Distearyl Phosphatidylglycerol	MiKasome [®] (NeXstar)
L-Alpha-Dimyristoylphosphatidylcholine	Abelcet [®] (The Liposome Co.)
L-Alpha-Dimyristoylphosphatidylglycerol	Abelcet [®] (The Liposome Co.)
Dioleoylphosphatidylcholine (DOPC)	DepoCyt [®] (Chiron)
Dipalmitoylphosphatidylglycerol (DPPG)	DepoCyt [®] (Chiron)
MPEG-distearoyl phosphoethanolamine	Doxil [®] (Sequus)
Diatrizoic acid	Conray [®] (Mallinckrodt)
Ethyl lactate	Ergotrate maleate (Lilly)
Ethylenediamine	Aminophylline (Abbott)
L-Glutamate sodium	Kabikinate [®] (Pharmacia-Upjohn)
Hydrogenated soy phosphatidylcholine	Doxil [®] (Sequus)
Iron ammonium citrate	Tice BCG [®] (Organon)
Lactic acid	Cipro IV [®] (Bayer)
D,L-Lactic and glycolic acid copolymer	Zoladex [®] (Zeneca)
Meglumine	Magnevist [®] (Berlex)
Niacinamide	Estradurin [®] (Wyeth-Ayerst)
Paraben methyl	Adriamycin RDF [®] (Pharmacia-Upjohn)
Protamine	Insulatard NPH [®] (Novo Nordisk)
Simethicone	Premarin Injection [®] (Wyeth-Ayerst)
Saccharin sodium	Compazine Injection [®] (Smith Kline Beecham)
Tri- <i>n</i> -butyl phosphate	Venoglobulin [®] (Alpha Therapeutic)
Triolein	DepoCyt [®] (Chiron)
von Willebrand factor	Bioclate [®] (Arco)
Zinc	Lente Insulin [®] (Novo Nordisk)
Zinc acetate	Nutropin Depot [®] (Genentech)
Zinc carbonate	Nutropin Depot [®] (Genentech)
Zinc oxide	Humalog [®] (Lilly)

16. von Willebrand factor is used to stabilize recombinant antihemophilic factor (Bioclate[®]).
17. Maltose serves as a tonicity adjuster and stabilizer in immune globulin formulation (Gamimune N[®]).
18. Epsilon amino caproic acid (6-amino hexanoic acid) is used as a stabilizer in anistreplase (Eminase Injection[®]).

19. Zinc and protamine have been added to insulin to form complexes and control the duration of action.

The FDA has published the “Inactive Ingredient Guide” which lists all excipients in alphabetical order (14). Each ingredient is followed by the route of administration, and

Table 10 List of excipients from the 1996 FDA Inactive Ingredient Guide

Benzyl chloride	Poloxamer 165
Butyl paraben	PEG 4000
Caldiamide sodium	Polyoxyethylene fatty acid esters
Calteridol calcium	Polyoxyethylene sorbitan monostearate
Cellulose (microcrystalline)	Polyoxyl 35 castor oil
Deoxycholic acid	Polysorbate 40
Dicyclohexyl carbodiimide	Polysorbate 85
Diethyl amine	Potassium hydroxide
Disofenin	Potassium phosphate, dibasic
Docusate sodium	Sodium bisulfate
Edamine	Sodium chlorate
Exametazime	Sodium hypochloride
Glucaptate sodium	Sodium iodide
Glucaptate calcium	Sodium pyrophosphate
Glucuronic acid	Sodium thiosulfate, anhydrous
Guanidine HCl	Sodium trimetaphosphate
Iofetamine HCl	Sorbitan monopalmitate
Lactobionic acid	Stannous chloride
Lidofenin	Stannous fluoride
Medrofenin	Stannous tartrate
Medronate disodium	Starch
Medronic acid	Succimer
Methyl boronic acid	Succinic acid
Methyl cellulose	Sulfurous acid
Methylene blue	Tetrakis (1-isocyano-2-methoxy-2-methyl-propionate) copper (I) Tc
<i>N</i> -(Carbamoyl-methoxy polyethylene glycol 2000)-1,2- distearoyl	Thiazoximic acid
<i>N</i> -2-Hydroxyethyl piperazine <i>N'</i> -2'-ethane sulonic acid	Urea
Nioxime	Zic acetate
Nitric acid	Zinc chloride
Oxyquinoline	2-ethyl hexanoic acid
Pentate (DTPA) calcium trisodium	PEG vegetable oil

in some cases, the range of concentration used in the approved drug product. However, this list does not provide the name of commercial product(s) corresponding to each excipient. Table 10 summarizes all the excipients included in the “Inactive Ingredient Guide” that do not appear in the Physician’s Desk Reference (PDR), GenRx, or Handbook of Injectable Drugs.

Similarly, in Japan the “Japanese Pharmaceutical Excipients Directory” is published by the Japanese Pharmaceutical Excipients Council, with the cooperation and guidance of the Ministry of Health and Welfare (47). This directory divides the excipients into:

1. *Official*. Those 590 excipients that have been recognized in the JP, Japanese Pharmaceutical Codex, and Japanese Pharmaceutical Excipients, and

for which testing methods and standards have been determined. Table 11 summarizes official excipients used in parenteral products.

2. *Nonofficial Excipients*. These 522 excipients are used in pharmaceutical products sold in Japan and will be included in the official book or in supplemental editions. The nonofficial excipients, used in parenteral products, are listed in Table 12.

REGULATORY PERSPECTIVE

The International Pharmaceutical Excipients Council (IPEC) has classified excipients into the following four classes, based on available safety testing information (48):

Table 11 Official Japanese pharmaceutical excipients

Name	Uses	Administration route
Acacia	Diluent, dispersing agent	im
Acetic acid	Buffer agent, solvent, stabilizer	iv, im, sc
L-Alanine	Stabilizer	iv, im,
Aluminum monostearate	Dispersing agent, stabilizer, vehicle	other inj.
Aluminum potassium sulfate	pH adjustment, stabilizer	im, sc
Aminoacetic acid	Buffering agent, solubilizer, stabilizer, suspending agent, vehicle	iv, im, sc, ic
Anhydrous citric acid	Buffer agent, pH adjustment, solubilizing agent, stabilizer	iv, im, other inj.
Anhydrous disodium hydrogen phosphate	Buffering agent, pH adjustment, solubilizer, stabilizer, suspending agent	iv, im, sc, other inj.
Anhydrous sodium dihydrogen phosphate	Buffering agent, pH adjustment, stabilizer	iv, im, other inj.
Arginine hydrochloride	Buffering agent, solubilizing agent, stabilizer	iv, im, sc
Ascorbic acid	Antioxidant, buffering agent, Stabilizer	iv, im, sc, ia
L-Aspartic acid	Solubilizer, stabilizer, vehicle	iv, im
Benzylkonium chloride	Buffering agent, preservative, stabilizer	
Benzethonium chloride	Dispersing agent, preservative, stabilizer	iv, im, other inj.
Benzoic acid	Buffering agent, preservative, stabilizer	iv, im
Benzyl alcohol	Preservative, solubilizer, solvent, stabilizer	iv, im, sc, ic, other inj.
Benzyl benzoate	Antiseptic, solubilizer, solvent	im
Calcium bromide	Isotonicity, stabilizer	iv
Calcium chloride	Isotonicity, suspending agent	iv
Calcium disodium edetate	Stabilizer	iv, ic, ia, is, other inj.
Calcium gluconate	Buffering agent, stabilizer	iv, im, sc
Calcium oxide	Solubilizing agent	iv
Calcium D-saccharate	Stabilizer	iv
Camellia oil	Solvent	im, sc
Carmellose sodium	Emulsifying agent, solubilizing agent, stabilizer, suspending agent	im, ic, sc, other inj.
Castor oil	Solubilizer, solvent	im
Chlorobutanol	Buffering agent, preservative	iv, im, sc
Citric acid	Antioxidant, buffering agent, pH adjustment, preservative, solubilizing agent, stabilizer	iv, im, sc, ia,
Concentrated glycerin	Isotonicity, solubilizer, stabilizer	iv, im, sc
Creatinine	Buffering agent, stabilizer	iv, im, ic, sc, other inj.
Cresol	Preservative	iv, im, sc
L-Cystine	Stabilizer	iv
Dehydrated ethanol	Solubilizer, solubilizing agent, solvent	iv, im, sc
Dextran 40	Stabilizer, vehicle	iv, im
Dextran 70	Stabilizer	sc
Dibasic potassium sulfate	Buffering agent, pH adjustment	iv, im, sc
Dibasic sodium citrate	Buffering agent, vehicle	iv
Dibasic sodium phosphate	Buffering agent, pH adjustment, solubilizing agent, stabilizer, vehicle	iv, im, sc, ia, is, ic, other inj.
Dilute hydrochloric acid	Buffering agent, pH adjustment, solubilizer, stabilizer	iv, im, sc
N, N-Dimethylacetamide	Solvent	iv

(Continued)

Table 11 Official Japanese pharmaceutical excipients (*Continued*)

Name	Uses	Administration route
Glucose	Buffering agent, isotonicity, solubilizer, stabilizer, vehicle	iv, im, sc, ic
Glycerin	Dispersing agent, isotonicity, preservative, solubilizing agent, solvent, stabilizer, suspending agent, vehicle	iv, im, sc, other inj.
Heparin sodium	Stabilizer	iv
L-Histidine	Stabilizer	iv
Hydrochloric acid	pH adjustment, solubilizing agent, stabilizer	iv, im, sc, ia, is, ic, other inj.
N-Hydroxyethyl lactamide solution	Solubilizing agent	iv
Hydroxypropylcellulose	Emulsifying agent, solubilizer, stabilizer, suspending agent, vehicle	im
Isotonic sodium chloride solution	Isotonicity, solvent	iv, im, sc, ia, ic, other inj.
Lactic acid	Buffering agent, pH adjustment, solubilizer, stabilizer,	iv, im, sc
Lactose	Dispersing agent, suspending agent, vehicle	iv, im, sc, ia, ic, other inj.
Lidocaine	Solubilizing agent, solvent	iv, im
L-Lysine-L-Glutamate	Solubilizing agent, stabilizer	iv
Lysine hydrochloride	Stabilizer	iv
Macrogol 400 (PEG 400)	Solubilizing agent	iv
Macrogol 4000 (PEG 4000)	Isotonicity, solubilizer, solvent, stabilizer, suspending agent, vehicle, wetting agent	iv, im, sc
Magnesium chloride	Isotonicity, solubilizing agent, stabilizer	iv
Magnesium gluconate	Stabilizer	iv
Magnesium sulfate	Stabilizer	iv, im, sc
Maleic acid	Buffering agent, pH adjustment, stabilizer	im
Maleic anhydride	Solubilizer, stabilizer	iv
Maltose	Stabilizer	iv, im, sc, ic, other inj.
D-Mannitol	Isotonicity, solubilizing agent, stabilizer	iv, im, sc, ic, other inj.
Meglumine	pH adjustment, solubilizing agent	iv
Mepylcaine hydrochloride	Soothing agent	iv, im, sc
Methanesulfonic acid	pH adjustment	im, sc
L-Methionine	Stabilizer	dental inj.
Methyl parahydroxybenzoate	Preservative, stabilizer	iv, im, sc, ic, other inj.
Monobasic potassium phosphate	Buffer agent, isotonicity, pH adjustment, solubilizing agent, stabilizer	iv, im, sc, ic
Monoethanolamine	Buffer agent, pH adjustment, solubilizer, stabilizer	iv
Monopotassium L-Glutamate monohydrate	Preservative, stabilizer	sc
Monosodium L-Glutamate monohydrate	Buffer agent	iv, im, sc
Nicotinamide	Isotonicity, solubilizing agent, stabilizer	iv, im, sc, other inj.
Peanut oil	Solubilizer, solvent, suspending agent, vehicle	im
Peptone, caesin	Stabilizer	sc
Phenol	Antiseptic, preservative	ic, im, sc, ic, other inj.

(Continued)

Table 11 Official Japanese pharmaceutical excipients (*Continued*)

Name	Uses	Administration route
Disodium edetate	Antioxidant, antiseptic, preservative, stabilizer	iv, ia, other inj.
Phosphoric acid	Buffer agent, isotonicity, pH adjustment, solubilizing agent, stabilizer	iv, im, sc
Polyoxyethylene hydrogenated castor oil 60	Dispersing agent, emulsifying agent, solubilizing agent, stabilizer, surfactant, suspending agent, vehicle	iv, im, sc
Polyoxyethylene hydrogenated castor oil 51	Dispersing agent, emulsifying agent, solubilizing agent	iv, im, sc, is
Polyoxyethylene [160] Polyoxypropylene [30] glycol	Dispersing agent, emulsifying agent, solubilizer, stabilizer, suspending agent, vehicle, surfactant, wetting agent	iv
Polysorbate 80	Dispersing agent, emulsifying agent, solubilizer, surfactant, stabilizer, suspending agent, vehicle, wetting agent	iv, im, sc, ic, other inj.
Potassium sulfate	Stabilizer	local anesthetic inj.
Powdered acacia	Dispersing agent, suspending agent	im, sc
Propylene glycol	Dispersing agent, isotonicity, preservative, solubilizer, solvent, stabilizer, suspending agent, vehicle, wetting agent	iv, im, sc
Propyl parahydroxybenzoate	Antiseptic, preservative, stabilizer	iv, im, sc, ic, other inj.
Protamine sulfate	Prolongating agent	sc
Purified gelatin	Base, stabilizer, suspending agent, vehicle	iv, im, sc
Purified soybean lecithin	Dispersing agent, emulsifying agent, solubilizer, stabilizer	iv
Purified yolk lecithin	Emulsifying agent	iv
Sesame oil	Base, solubilizing agent, solvent, stabilizer, vehicle	iv, im, sc, other inj.
Sodium acetate	Buffer agent, pH adjustment, solubilizing agent, stabilizer	iv, im, sc, other inj.
Sodium acetyl tryptophan	Stabilizer	iv, sc
Sodium benzoate	Antiseptic, buffer agent, preservative, solubilizer, stabilizer	im
Sodium bicarbonate	Buffer agent, isotonicity, pH adjustment, solubilizer, stabilizer	iv, im, sc, is, ic, other inj.
Sodium bisulfite	Antioxidant, isotonicity, stabilizer	iv, im, sc, other inj.
Sodium bromide	Isotonicity	iv, im, sc
Sodium caprylate	Stabilizer	iv, sc
Sodium carbonate	Buffer agent, pH adjustment, solubilizing agent, stabilizer	iv, im, sc
Sodium chloride	Base, buffering agent, isotonicity, solubilizer, stabilizer, suspending agent, vehicle	iv, im, sc, ia, is
Sodium chondroitin sulfate	Stabilizer	iv
Sodium citrate	Antiseptic, buffer agent, isotonicity, pH adjustment, solubilizer, stabilizer	iv, im, sc, ic, ia, is, other inj.
Sodium desoxycholate	Solubilizing agent	ic, iv, is
Sodium dihydrogen phosphate dihydrate	Buffer agent, isotonicity, pH adjustment, stabilizer	iv, im, sc, ia, is, other inj.
Sodium formaldehydesulfoxylate	Stabilizer, isotonicity, pH adjustment	iv, im
Sodium hydroxide	Solubilizer	iv, im, sc, ia, ic, other inj.

(Continued)

Table 11 Official Japanese pharmaceutical excipients (*Continued*)

Name	Uses	Administration route
Sodium salicylate	Antiseptic, preservative, solubilizing agent, stabilizer	iv, im, sc
Sodium thiomalate	Antioxidant, stabilizer	im
Sodium thiosulfate	Solubilizer, stabilizer	iv, im, sc
Sorbitan sesquioleate	Base, emulsifying agent, solubilizing agent, stabilizer, surfactant, vehicle	iv, im
D-Sorbitol	Dispersing agent, isotonicity, plasticizer, preservative, solubilizing agent, stabilizer	iv, im, sc, other inj.
D-Sorbitol solution	Base, isotonicity, solubilizing agent, stabilizer, vehicle	im, sc, other inj
Soybean oil	Base, solubilizer, solvent, vehicle	iv
Stannous chloride	Reducing agent	iv
Sucrose	Base, stabilizer, vehicle	iv, sc
Tartaric acid	Buffering agent, pH adjustment, solubilizing agent, stabilizer, vehicle	iv, im
Thimerosal	Preservative	iv, im, sc
Thioglycolic acid	Solubilizing agent, stabilizer	iv, im, sc
Tribasic sodium phosphate	Buffering agent, pH adjustment	iv, im, sc
Trometamol (Tromethamine)	Buffering agent, solubilizing agent, stabilizer	iv, im, sc, ia, is, ic
Urea	Solubilizing agent, stabilizer, wetting agent	iv, im, sc
Water for injection	Solubilizer, solvent	iv, im, sc, ia, is, ic, other inj.
Xylitol	Isotonicity, stabilizer, vehicle	iv, im, other inj.
Zinc acetate	Stabilizer	sc
Zinc chloride	Stabilizer	im, sc
Zinc oxide	Dispersing agent, stabilizer, vehicle	sc

1. *New chemical excipients*: Require a full safety evaluation program. The estimated cost of safety studies for a new chemical excipient is approximately \$35 million over 4–5 years. European Union (EU) directive 75/318/EEC states that new chemical excipients will be treated in the same way as new actives. In the United States a new excipient requires a Drug Master File (DMF) to be filed with the FDA. Similarly, in Europe a dossier needs to be established. Both the DMF and dossier contain relevant safety information. The IPEC Europe has issued a draft guideline (Compilation of Excipient Masterfiles Guidelines) which provides guidance to excipient producers on how to construct a dossier that will support a Marketing Authorization Application (MAA) while maintaining the confidentiality of the data.
2. *Existing chemical excipient—first use in man*: Implies that animal safety data exist since data may have been used in some other application. Additional safety information may have to be gathered to justify its use in humans.

3. *Existing chemical excipient*: Indicates that it has been used in humans but change in route of administration (say from oral to parenteral), new dosage form, higher dose, etc. may require additional safety information.
4. *New modifications or combinations of existing excipients*: A physical interaction NOT a chemical reaction. No safety evaluation is necessary in this case.

Simply because an excipient is listed as Generally Recognized As Safe (GRAS) does not mean that it can be used in parenteral dosage form. The GRAS list may include materials that have been proven safe for food (oral administration) but have not been deemed safe for use in an injectable product. This makes it difficult for the formulation development scientist to choose additives during the dosage form development.

Many pharmacopeial monographs for identical excipients differ considerably with regards to specifications, test criteria, and analytical methods. Thus, if a pharmaceutical manufacturer is going to supply a product

Table 12 Non-official Japanese pharmaceutical excipients

Excipients	Uses	Administration
Aluminum chloride	Potentiating agent	im, sc
Aluminum hydroxide	Adsorbent	sc, im
Aminoethyl sulfonic acid	Buffer, isotonicity, stabilizer, vehicle	iv, im
Ammonium acetate	pH adjusting agent	im
Anhydrous stannous chloride	Reducing agent	iv
L-Arginine	Buffer, stabilizer, solubilizer	iv, im, sc
Asepsis sodium bicarbonate	Stabilizer	iv
Butylhydroxyanisol	Antioxidant, stabilizer	iv
<i>m</i> -Cresol	Preservative	iv, im, sc, ic
L-Cysteine	Stabilizer	iv
Cysteine hydrochloride	Antioxidant, stabilizer	iv, im
Dichlorodifluoromethane	Propellant	iv
Diethanolamine	Buffer, solubilizer, stabilizer	iv
Diethylenetriaminepentaacetic acid	Stabilizer	iv
Ferric chloride	Stabilizer	iv
Highly purified yolk lecithin	Emulsifier	iv
Human serum albumin	Preservative, stabilizer	iv, im, sc
Hydrolyzed gelatin	Stabilizer	sc
Inositol	Stabilizer, vehicle	iv, im
Lidocaine hydrochloride	Soothing agent	im
D,L-Methionine	Stabilizer	im, sc
Monobasic sodium phosphate	Buffer, isotonicity, adjust pH	iv, im, sc
Oleic acid	Dispersing agent, solvent	iv
Phenol red	Coloring agent	sc
Polyoxyethylene castor oil	Base, emulsifying agent, solubilizing agent, stabilizer	iv
Polyoxyethylene hydrogenated castor oil	Base, emulsifying agent, solubilizer, stabilizer, suspending agent, vehicle	iv
Polyoxyethylene sorbitan monolaurate	Emulsifying agent, solubilizing agent, surfactant	iv, im, sc
Potassium pyrosulfite	Stabilizer	iv, sc, im
Potassium thiocyanate	Stabilizer	iv
Purified soybean oil	Solubilizer	iv
Sodium acetate, anhydrous	Buffer, pH adjuster, solubilizing agent, stabilizer	im
Sodium carbonate, anhydrous	Buffer, solubilizing agent	iv, im, ic
Sodium dihydrogen phosphate monohydrate	Buffering agent	ic
Sodium gluconate	Stabilizer, vehicle	iv, im
Sodium pyrophosphate, anhydrous	Dispersing agent, isotonicity, stabilizer	iv, im, is
Sodium sulfite	Antioxidant, stabilizer	iv
Sodium thioglycolate	Antioxidant, stabilizer	iv, im, sc
Sorbitan esters of fatty acids	Emulsifying agent, solubilizing agent, surfactant, stabilizer, suspending agent, vehicle	iv
Succinic acid	pH adjusting agent	iv
α -Thioglycerol	Antioxidant	iv, im, sc
Triethanolamine	Buffer, pH adjuster, solubilizing agent, stabilizer	iv
Zinc chloride solution	Stabilizer	sc

throughout the world, the manufacturer will have to repeat testing on the same excipient several times in order to meet USP, JP, EP, BP, and other pharmacopoeias. EP, JP and

USP are the main driving bodies within the International Conference on Harmonization (ICH) that are working on several of the commonly used excipients in order to

achieve a single monograph for each excipient. For example, benzyl alcohol undergoes degradation by a free radical mechanism to form benzaldehyde and hydrogen peroxide. The degradation products are much more toxic than the parent molecule. The *USP*, *JP*, and *EP* require three different chromatographic systems to test for organic impurity (mainly benzaldehyde). The harmonized monograph of benzyl alcohol will eliminate unnecessary repetition, which does not contribute to the overall quality of the product (49). The following 11 pharmacopoeial tests can be substituted by a single gas chromatography (GC) method:

EP:

- Benzaldehyde, related substance (GC)
- Halogenated compounds and halides (colorimetric test)
- Assay (hydroxyl value)

JP:

- Limit test for benzaldehyde
- Limit test for chlorinated compounds
- Distillation range Assay (hydroxyl value)

NF/USP:

- Benzaldehyde (HPLC)
- Halogenated compounds and halides (colorimetric test)
- Organic volatile impurities (GC)
- Assay (hydroxyl value)

The harmonization process is just beginning and is a major step in the right direction.

Another area where regulatory bodies are focusing their attention is the manufacturing process used to produce excipients. The IPEC has undertaken major initiatives to improve the quality of additives and has published "Good Manufacturing Practices Guide for Bulk Pharmaceutical Excipients" (50). The excipients may be manufactured for the food, cosmetic, chemical, agriculture, or pharmaceutical industries, and the requirements for each area are different. The purpose of this guide is twofold: 1) to develop a quality system framework that can be used for suppliers of excipients and which will be acceptable to the pharmaceutical industry, and 2) to harmonize the requirements in the United States, Europe, and Japan.

The United States, Europe, and Japan require that all excipients be declared on the label if the product is an injectable preparation. The European guide for the label and package leaflet also lists excipients, that have special issues. These are addressed in an Annex (51). Table 13 contains a summary of some of these ingredients, which are commonly used as parenteral excipients and the corresponding safety information that

should be included in the leaflet. Similarly, 21 CFR 201.22 requires prescription drugs containing sulfites to be labeled with a warning statement about possible hypersensitivity. An informational chapter in USP <1091> entitled "Labeling of Inactive Ingredients" provides guidelines for labeling of inactive ingredients present in dosage forms.

CRITERIA FOR THE SELECTION OF EXCIPIENT AND SUPPLIER

During the development of parenteral dosage forms, the formulator selects excipients that will provide a stable, efficacious, and functional product. The choice, and the characteristics of excipients should be appropriate for the intended purpose.

An explanation should be provided with regard to the function of all constituents in the formulation, with justification for their inclusion. In some cases, experimental data may be necessary to justify such inclusion, e.g., preservatives. The choice of the quality of the excipient should be guided by its role in the formulation and by the proposed manufacturing process. In some cases, it may be necessary to address and justify the quality of certain excipients in the formulation (52).

Normally, a pharmaceutical development report is written in the United States, which should be available at the time of Pre-Approval Inspection (PAI). The development report contains the choice of excipients, their purpose and levels in the drug product, compatibility with other excipients, drug or package system, and how they may influence the stability and efficacy of the finished product.

The following key points should be considered in selecting an excipient and its supplier for parenteral products:

1. Influence of excipient on the overall quality, stability, and effectiveness of drug product.
2. Compatibility of excipient with drug and the packaging system.
3. Compatibility of excipient with the manufacturing process. For example, preservatives may be adsorbed by rubber tubes or filters, acetate buffers will be lost during lyophilization process, etc.
4. The amount or percentage of excipients that can be added to the drug product. Table 6 summarizes the maximum amount of preservatives and antioxidants allowed by various pharmacopoeias.

Table 13 Excipients for label and corresponding information for leaflet

Name	Information on leaflet
Arachis oil	Whenever arachis oil appears, peanut oil should appear beside it (because some individuals are sensitive to peanuts)
Benzoic acid and benzoates	It may increase the risk of jaundice in newborn babies
Benzyl alcohol	Contraindicated in infants or young children; up to 3 years old
Boric acid its salts and esters	Contraindicated in infants or young children; up to 3 years old
Dimethyl sulfoxide	Can cause stomach upset, diarrhea, drowsiness, and headache
Lactose	Unsuitable for people with lactose insufficiency, galactosemia, or glucose/galactose malabsorption syndrome
Organic mercury compounds	Can cause kidney damage
Parahydroxybenzoate and their esters	Known to cause urticaria. Generally delayed type reactions, such as contact dermatitis
Phenylalanine	Harmful for people with phenylketonuria
Polyethoxylated castor oils	Warning for parenterals only—hypersensitivity, drop in blood pressure, inadequate circulation, dyspnea, hot flushes
Potassium	For products administered iv—can cause pain at the site of injection or phlebitis
Sodium	May be harmful to people on low sodium diet
Sorbitol	Unsuitable in hereditary fructose intolerance
Sucrose (saccharose)	Unsuitable in hereditary fructose intolerance, glucose/galactose malabsorption syndrome, or sucrase-isomaltase deficiency
Sulphites (metabisulphites)	Can cause allergic-type reactions including anaphylactic symptoms and bronchospasm in susceptible people, especially those with a history of asthma or allergy
Urea	For products given iv—may cause venous thrombosis or phlebitis

- Route of administration. The *USP*, *EP*, and *BP* do not allow preservatives to be present in injections intended to come in contact with brain tissues or CSF. Thus intracisternal, epidural, and intradural injections should be preservative free. Also, it is preferred that a drug product to be administered via intravenous (iv) route be free of particulate matter. However, if the size of the particle is well controlled, like in fat emulsion or colloidal albumin or amphotericin B dispersion, it can be administered by iv infusion.
- Dose volume. All LVPs and those SVPs where the single dose injection volume can be greater than 15 ml are required by the *EP/BP* to be preservative free (unless justified). The *USP* recommends that special care be observed in the choice and the use of added substances in preparations for injections that are administered in volumes exceeding 5 ml.
- Whether the product is intended for single or multiple dose use. According to *USP*, single dose injections should be free of preservative. The *FDA* takes the position that even though a single dose injection may have to be aseptically processed, the manufacturer should not use a preservative to prevent microbial growth. European agencies have taken a more lenient attitude on this subject.
- The length or duration of time that the drug product will be used once the multidose injection is opened.
- How safe is the excipient?
- Does the parenteral excipient contain very low levels of lead, aluminum, or other heavy metals?
- Does a dossier or DMF exist for the excipient?
- Has the excipient been used in humans? Has it been used via a parenteral route and in the amount and concentration that is being planned?
- Has the drug product that contains this excipient been approved throughout the world?
- What is the cost of the excipient and is it readily available?
- Is the excipient vendor following the *IPEC GMP* guide? Is the vendor *ISO 9000* certified?
- Will the excipient supplier certify the material to meet *USP*, *BP*, *EP*, *JP*, and other pharmacopoeias?
- Has the supplier been audited by the *FDA* or the company's audit group? How did it fare?

Presence of impurities in excipients can have a dramatic influence on the safety, efficacy or stability of the drug product. Monomers or metal catalysts used during a polymerization process are toxic and can also destabilize the drug product if present in trace amounts. Due to safety

concerns, the limit of vinyl chloride (monomer) in polyvinyl pyrrolidone is nmt 10 ppm, and for hydrazine (a side product of polymerization reaction) nmt 1 ppm. Monomeric ethylene oxide is highly toxic and can be present in ethoxylated excipients such as PEGs, ethoxylated fatty acids, etc.

The FDA has issued a guidance suggesting that animal-derived materials such as egg yolk lecithin, and egg phospholipid) used in drug products, originating from Belgium, France, and the Netherlands between January and June 1999 should be investigated for the presence of dioxin and polychlorinated biphenyls. The contamination in the animal-derived product was probably due to contaminated animal feed.

Excipients manufactured by fermentation processes, such as dextrose, citric acid, mannitol, and trehalose, should be specially controlled for endotoxin levels. Mycotoxin (highly toxic metabolic products of certain fungi species) contamination of an excipient derived from natural material has not been specifically addressed by regulatory authorities. The German health authority issued a draft guideline in 1997 where a limit was specified for Aflatoxins M₁, B₁, and the sum of B₁, B₂, G₁, and G₂ in the starting material for pharmaceutical products.

Heavy metal contamination of excipients is a concern, especially for sugars, phosphate, and citrate. Several rules have been proposed or established. For example, the EP sets a limit of nmt 1 ppm of nickel in polyols. California Proposition 65 specifies a limit of nmt 0.5 µg of lead per day per product (53). Similarly, the FDA has proposed a guideline that would limit the aluminum content for all LVPs used in TPN therapy to 25 µg/L (54). Furthermore, it requires that the maximum level of aluminum in SVPs intended to be added to LVPs and pharmacy bulk packages, at expiration date, be stated on the immediate container label.

Physical and chemical stability of the excipient should be considered in assigning a reevaluation date. Since many drug products have a small amount of active and a comparatively high amount of excipients, degradation of even a small percentage of excipient can lead to levels of impurities sufficient to react or degrade a large percentage of active material. For example, benzyl alcohol decomposes via free radical mechanism in the presence of light and oxygen, to form benzaldehyde (x% of benzaldehyde is approximately equivalent to 1/3 x% of hydrogen peroxide). Hydrogen peroxide can rapidly oxidize sulfhydryl groups of amino acids such as cysteine present in peptides or proteins.

It is essential that adequate research and thought be given in the selection of a pharmaceutical excipient

supplier. It is not uncommon for the supplier to change its manufacturing process to make products more efficiently (i.e., less costly). Normally, excipients are low-value, high-volume products that are used by several industries. The pharmaceutical industry, in general, is not the major customer of excipients (in terms of volume of material purchased). For example, the pharmaceutical industry uses approximately 20% of gelatin produced. Of this 20%, most is for production of oral dosage forms. The parenteral portion is approximately 5% of this 20%. Therefore, it is extremely important that the drug manufacturer has a contract with the excipient supplier, that prohibits the supplier from making any change in the process/quality of the material without informing their customers well in advance. Also, the pharmaceutical manufacturer should investigate all the alternate sources that could be used in case of an emergency. A change in the supplier should not be made without consulting the pertinent regulatory bodies, since such an event may require prior regulatory approval.

The pharmaceutical manufacturer should have an active Vendor Certification Program. The manufacturer also should assure that the vendor is ISO 9000 certified. An audit of the excipient manufacturer is essential, since the pharmaceutical industry is ultimately responsible for the quality of the drug product that includes the excipient(s) as one of the components. The IPEC GMP guide may be used as an audit tool, since it is written in the format of ISO 9000 using identical nomenclature and paragraph numbering. The audit may ensure that the quality is being built into the excipient that may be difficult to measure later by quality control on receipt of the material. This is especially true for parenteral excipients where not only chemical, but also microbiological attributes are critical. Bioburden and endotoxin limits may be needed for each of the excipients and several guidelines are available to establish the specifications (55, 56).

Recent events in Haiti highlight the importance of assuring the quality of excipients to the same degree that one normally does for active ingredients. From November 1995 through June 1996, acute anuric renal failure was diagnosed in 86 children. This was associated with the use of diethylene glycol-contaminated glycerin used to manufacture acetaminophen syrup (57).

SAFETY ISSUES

Reference 58 is an excellent resource on the safety and adverse reaction to several excipients. Sensitization reactions have been reported for the parabens, thimerosal,

and propyl gallate. Sorbitol is metabolized to fructose and can be dangerous when administered to fructose-intolerant patients. Table 13 also lists safety concerns.

Progress in drug delivery systems and new protein-s/peptides being developed for parenteral administration has created a need to expand the list of excipients that can be safely used. An informational chapter included in the USP 24, presents a scientifically based approach for safety assessment of new pharmaceutical excipients (59). This chapter is based on the excipient safety evaluation guidelines prepared by The Safety Committee of the International Pharmaceutical Excipient Council, with appropriate redaction. Table 14 summarizes the approach in developing a new excipient.

Currently, there are some concerns regarding Transmissible Spongiform Encephalopathies (TSE) via animal-derived excipients such as gelatin. TSEs are caused by prions that are extremely resistant to heat and normal sterilization processes. TSEs have a very long incubation time with no cure and include diseases such as the following:

- Scrapies in sheep and goats
- Bovine spongiform encephalopathy (BSE), otherwise known as Mad Cow Disease, in cattle
- Kuru disease in humans
- Creutzfeld-Jacob disease (CJD) in humans, which has been attributed to repeated parenteral administration of growth hormone and gonadotropin derived from human pituitary glands.

Several guidelines have been issued that address the issue of animal-derived excipients and scientific principles to minimize the possible transmission of TSEs via medicinal products (60, 61). The current situation indicates that there are negligible concerns for lactose, glycerol, fatty acids, and their esters, but the situation is less clear for gelatin. In this scenario, if one has a choice, then it may be beneficial to select nonanimal-derived excipients. The use of bovine serum albumin (BSA) or human serum albumin (HSA) is of concern because they can be derived from virus-contaminated blood. The risk of TSEs from excipients can be greatly reduced by controlling the following parameters:

1. Source of animal should be from countries where BSE has not been reported.
2. Animals used should be young.
3. Category III or IV animal tissue should be used in manufacture (60).
4. A production process that is likely to destroy TSE agents should be utilized.

Table 14 Summary of safety evaluation of excipient

Tests	Injectable route ^a
Baseline toxicity data	
Acute oral toxicity	Required
Acute dermal toxicity	Required
Acute inhalation toxicity	Conditional
Eye irritation	Required
Skin irritation	Required
Skin sensitization	Required
Acute injectable toxicity	Required
Application site evaluation	Required
Phototoxicity/photoallergy	Required
Genotoxicity assays	Required
ADME/PK-intended route	Required
28-day toxicity (2 species) intended route	Required
Additional data: Short or intermediate term repeated use	
90-day toxicity (most appropriate species)	Required
Embryo-fetal toxicol	Required
Additional assays	Conditional
Genotoxicity assays	Required
Immunosuppression assays	Required
Additional data: Intermittent long-term or chronic use	
Chronic toxicity (rodent, nonrodent)	Conditional
Reproductive toxicity	Required
Photocarcinogenicity	Conditional
Carcinogenicity	Conditional

^aTerm injectable includes routes such as iv, sc, intrathecal, etc.

Amendment to the European Commission directive 75/318/EEC would require manufacturers to provide a “Certificate of Suitability” or the underlying “scientific information” in the form of a marketing variation to attest that their pharmaceuticals are free of TSEs.

FUTURE DIRECTION

Several new excipients are being evaluated in order to increase the solubility or improve the stability of parenteral drugs. Cyclodextrins have been tried for the above reasons. Currently, there are two FDA approved parenteral products that have utilized α and γ -cyclodextrins. β -cyclodextrin is unsuitable for parenteral administration because it causes necrosis of the proximal kidney tubules upon IV and subcutaneous administration (62). Hydroxypropyl β -cyclodextrin (HP β CD) and sulfobutylether β -cyclodextrin

(SBE-7- β -CD) have shown the most promise. CaptisolTM is the trade name of SBE-7- β -CD and is anionic. Currently, two CaptisolTM based small molecule IV and IM drug formulations are in Phase III clinical trials in the United States. One parenteral formulation that utilizes HP β CD (Cavitron[®]) is in Phase II/III clinical trials, and another (Sporanox) has been approved by the FDA. Manufacturers of HP β CD and SBE-7- β -CD have established a DMF with the FDA. A detailed review of cyclodextrins was recently published (63, 64). It should be noted, however, that cyclodextrin also can accelerate the degradation of drug product (65) and can sequester preservatives, rendering them ineffective (66).

Chitosan, β -1,4-linked glucosamine, is a naturally occurring, biodegradable, nontoxic polycationic biopolymer. It is being investigated for its potential as a cross-linked matrix of microspheres to deliver antineoplastic drugs. Because of its charge, it can trap several drugs and can bind strongly with cancer cells, thereby minimizing drug toxicity and enhancing therapeutic efficacy (67). Chitosan also has been shown to stabilize liposomes.

Biodegradable polymeric materials such as polylactic acid, polyglycolic acid, and other poly-alpha-hydroxy acids have been used as medical devices and as biodegradable sutures since the 1960s (68). Currently, the FDA has approved for marketing, only devices made from homopolymers or copolymers of glycolide, lactide, caprolactone, *p*-dioxanone, and trimethylene carbonate (69). Such biopolymers are finding increased application as a matrix to deliver parenteral drugs for prolonged delivery (70). At least four drug products—Lupron Depot[®], Decapeptyl[®], Nutropin Depot[®], and Zoladex[®]—have been approved. These four drug products are microspheres in PLG, polylactic acid (PLA), or the PLGA matrix. Polyglycolic acid (PGA) is highly crystalline (approximately 50%) with a high melting point (220–225°C). PLA can be produced by the polymerization of L-lactic acid (LPLA), D-lactic acid (DPLA), or a blend of D- and L- lactic acid (DLPLA). LPLA is 37% crystalline while DLPLA, is amorphous. The degradation time of LPLA is much slower than that of DPLA requiring more than 2 years. By copolymerizing lactic and glycolic acid, polymeric matrices with a wide range of properties (tensile strength, crystallinity, and degradation rate) can be obtained. Decapeptyl[®] is approved in France and is a microsphere for IM administration. It contains drug in a matrix of PLGA and Carboxymethyl cellulose with mannitol and polysorbate 80.

Polyanhydrides degrade primarily by surface erosion and possess excellent in vivo compatibility. In 1996 the

FDA approved a polyanhydride-based drug delivery system to the brain of chemotherapeutic agent BCNU, which is currently being manufactured by Guilford Pharmaceutical, Inc.

Several phospholipid-based excipients are finding increased application as solubilizing agents, emulsifying agents, or as components of liposomal formulation. The phospholipids occur naturally and are biocompatible and biodegradable. Examples include egg phosphatidylcholine, soybean phosphatidylcholine, hydrogenated soybean phosphatidylcholine (HSPC), DMPC, DSPC, DOPC, DSPE, DMPG, DPPG, and DSPG. SpartajectTM technology uses a mixture of phospholipids, to encapsulate poorly water-soluble drugs, to form micro-suspensions that can be injected intravenously. Busulfan[®] drug product uses this technology and is currently undergoing Phase I clinical trials. Many liposomal and liposomal-like formulations (DepoFoam[®]) are either approved (Depo-Cyt[®]) or are undergoing clinical trials to reduce drug toxicity, improve drug stability, prolong the duration of action, or to deliver drug to the central nervous system (71). Two amphotericin formulations have been approved in the United States. They are liposomal, or a lipid complex between the antifungal drug and positively charged lipid. Amphotec[®] is a 1:1 molar ratio complex of amphotericin B and cholesteryl sulfate while Abelcet[®] is a 1:1 molar complex of amphotericin B with phospholipids (seven parts of L- α -dimyristoylphosphatidylcholine and L- α -dimyristoylphosphatidyl glycerol).

Poloxamers or pluronics are block copolymers comprised of polyoxyethylene and polyoxypropylene segments. They exhibit reverse thermal gelation and are being tried as solubilizing, emulsifying, and stabilizing agents. Thus, a depot drug delivery system can be created using pluronics whereby the product is a viscous injection that gels upon IM injection (72). Pluronic can prevent protein aggregation or adsorption/absorption and can help in the reconstitution of lyophilized products. Pluronic F68 (Polaxamer-188), F38 (Poloxamer-108), and F127 (Poloxamer-407) are the most commonly used pluronics. For example, liquid formulation of human growth hormone and Factor VIII can be stabilized using pluronics. Fluosol[®] is a complex mixture of perfluorocarbons, with a high oxygen-carrying capacity emulsified with Pluronic F-68, and various lipids. It was recently approved by the FDA for adjuvant therapy to reduce myocardial ischemia during coronary angioplasty. A highly purified form of Poloxamer 188 (FlocorTM), intended for IV administration, is undergoing Phase III clinical trials for various cardiovascular diseases. Purification of Poloxamer 188 has been shown to reduce nephrotoxicity.

Poloxamers and other polymeric materials such as albumin may coat the micro- or nano particle, alter their surface characteristics and reduce their phagocytosis and opsonization by the reticuloendothelial system following IV injection. Such surface modifications often result in prolongation in the circulation time of intravenously injected colloidal dispersions (73). Poloxamers also have been used to stabilize suspension such as NanoCrystal™ (74).

The first successful development of an injectable perfluorocarbon-based commercial product was achieved by the Green Cross Corporation in Japan, when it made Fluosol-DA®, a dilute (20% w/v) emulsion based on perfluorodecalin and perflurotripropylamine emulsified with potassium oleate, Pluronic F-68, and egg yolk lecithin. These perfluorocarbons are inert and also can be used to formulate nonaqueous preparations of insoluble proteins and small molecules (75). Perfluorocarbons also have been approved by the FDA for use in one ultrasound contrast agent, Optison®, which is administered via the IV route. Optison® is a suspension of microspheres of HSA with octafluoropropane. Heat treatment and sonication of appropriately diluted human albumin, in the presence of octafluoropropane gas, is used to manufacture microspheres in the Optison® injection. The protein in the microsphere shell makes up approximately 5–7 (wt%) of the total protein in the liquid. The microspheres have a mean diameter range of 2.0–4.5 µm with 93% of the microsphere being less than 10 µm.

Sucrose acetate isobutyrate (SAIB) is a high viscosity liquid system that converts into free-flowing liquid when mixed with 10–15% ethanol (76). On subcutaneous or IM injection, the matrix rapidly converts to a water-insoluble semi-solid, that is capable of delivering proteins and small molecules for a prolonged period. SAIB is biocompatible, and biodegrades to natural metabolites. This is a fairly new matrix and three INDs have been filed for veterinary applications. It has not been used in humans.

Several other biodegradable, biocompatible, injectable polymers are being investigated for drug delivery systems. They include polyvinyl alcohol, block copolymer of PLA–PEG, polycyanoacrylate, polyanhydrides, cellulose, alginate, collagen, gelatin, albumin, starches, dextrans, hyaluronic acid and its derivatives, and hydroxyapatite (77).

EXCIPIENTS—SAFETY TESTING

Marshall Steinberg

International Pharmaceutical Excipients Council-Americas, Arlington, Virginia, U.S.A.

Florence K. Kinoshita

Hercules Incorporated, Arlington, Virginia, U.S.A.

INTRODUCTION

The safety issues concerning pharmaceutical excipients can be classified into three categories: quality, toxicology, and improper use (1). Various regulatory directives address the quality category. In addition, the International Pharmaceutical Excipient Council's (IPEC) guideline publications address this issue by following the Organization of International Standardization (ISO) 9000 structure. IPEC is an industry association with worldwide membership that includes over 200 pharmaceutical, chemical, and food processing firms that develop, manufacture, sell, and use pharmaceutical excipients. IPEC comprises three regional organizations located in the United States, Europe, and Japan each with the same objectives.

Quality

The aforementioned IPEC guidelines that address quality include:

- Good Manufacturing Guide for Bulk Pharmaceutical Excipients
- Good Manufacturing Practices (GMP) Audit Guideline for Distributors of Bulk Pharmaceutical Excipients
- IPEC-Americas Significant Change Guide for Bulk Pharmaceutical Excipients
- GMP Audit Guideline for Suppliers of Bulk Pharmaceutical Excipients
- New Excipient Safety Evaluation Guidance
- IPEC-Americas Guide for the Development of an Impurity Profile
- Format and Required Content of Certificates of Analyses

The IPEC-Americas Safety Guidelines (modified) are presented as an information chapter in United States Pharmacopoeia (USP) 24/NF 19 (2). The Good Manufacturing Guide or Practices for Bulk Pharmaceutical

Excipients also has been published as an information chapter in USP 24/NF 19. The guideline also serves as a basis for the World Health Organization (WHO) guidance to its national members (3). The intention of IPEC is to ensure that these guidelines reflect the concerns and intentions of responsible parties in the United States, the European Union (EU), and Japan. In other words, the guidelines are harmonized so that excipients that meet the requirements of a harmonized monograph can be sold and used in these three areas of the world. The use of these and other national guidelines ensure the quality of excipients.

These guidelines, using an ISO 9000 format, not only provide a way to assess whether systems are in place, but provide a means for evaluating the effectiveness of the systems. They also provide guidance on how to conduct an audit of a manufacturing operation that produces excipients (4) and in turn, give guidelines on auditing their distribution and repackaging (5).

International Conference on Harmonization Residual Solvent Guidance

Excipient impurity profiles and how to evaluate this important aspect of excipient manufacture, particularly in light of the International Conference on Harmonization (ICH) guidance published in 1999 (6), also are addressed. Care must also be taken that residual solvent levels do not exceed those proscribed in the ICH Guidance for Residual Solvents published in 1999. Solvents are divided into three classes:

1. *Class 1 solvents: Solvents to be avoided.* These include known human carcinogens, strongly suspected human carcinogens, and environmental hazards.
2. *Class 2 solvents: Solvents to be limited.* These include nongenotoxic animal carcinogens or possible causative agents of other irreversible toxicity, such as neurotoxicity or teratogenicity and solvents suspected of other significant but reversible toxicities.

3. *Class 3 solvents: Solvents with low toxic potential.* These include solvents with low toxic potential to man; no health-based exposure limit is needed. Class 3 solvents have permitted daily exposures of 50 mg or more per day.

IPEC Significant Change Guidance

Two areas of concern to excipient makers and users have been those of significant change and certificates of analyses. Any change by the manufacturer of an excipient that alters an excipient's physical or chemical property from the norm or that is likely to alter the excipient's performance in the dosage form is considered significant (7). Regardless of whether there is a regulatory requirement to notify the local regulatory authority, the manufacturer has an obligation to notify its customers of significant change so that the customer can evaluate the change on the customer's products. The Significant Change Guidance establishes uniform considerations for evaluating significant changes involving the manufacture of bulk excipients. The types of changes that might be considered include:

- Site
- Scale
- Equipment
- Process
- Packaging
- Specifications

The requirement for evaluating the impact of change on the excipient begins at the processing step from which GMP compliance begins, as noted in the IPEC Good Manufacturing Guide or Practices Guide for Bulk Pharmaceutical Excipients, or later in the process.

The evaluation criteria in the guideline include:

1. Changes in the chemical properties of the excipient owing to the change
2. Changes in the physical properties of the excipient owing to the change
3. Changes in the impurity profile of the excipient owing to the change
4. Changes in the functionality of the excipient owing to the change
5. Changes in the moisture level of the excipient owing to the change
6. Changes in the bioburden of the excipient owing to the change

The guideline also provides for consideration of objective criteria when considering changes to the

impurity profile of an excipient as a result of any change. IPEC-Americas has developed a guide for the preparation of an impurity profile for excipients. The profile addresses the following:

1. All specified organic impurities
2. Unidentified organic impurities at or above 0.1% whether specified or not, unless the impurity has an established pharmacological effect or is known to be unsafe at a lower level
3. Residual solvents
4. Inorganic impurities
5. Toxic impurities

The content of the impurity profile varies with the nature of the excipient, the raw materials used in its manufacture, and its chemical composition. Changes are considered significant whenever a new impurity is introduced at or above the 0.1% concentration or when an impurity previously present at or above 0.1% disappears.

IPEC Certificate of Analysis Guidance

The second issue involves the certificate of analysis that the manufacturer must provide to the formulator when shipping the excipient. Most often, a certificate of analysis does not contain information developed as a result of analysis of the specific batch of material being delivered. The analysis may have either been conducted on previous individual batches or on a mixture of aliquots of previous batches. No guidelines regarding exactly what should be found in the certificate and how it should be presented have been established. This is addressed in the guideline (8). At the time of this writing, the frequency of sampling has not been resolved with the U.S. Food and Drug Administration (FDA). Some believe that in the face of no significant changes it should not be necessary to sample each manufactured batch, but that there is a need only for sufficient sampling to ensure that statistical significance of sampling results can be met. What to do if the manufacturing process is continuous rather than a batch process would fall under the same criteria except that the sampling frequency would probably be based on time/volume rather than batches.

EXCIPIENT USAGE

There are roughly 8000 "nonactive" ingredients being used in food, cosmetics, and pharmaceuticals worldwide (1). In 1996, approximately 800 excipients were used in

marketed pharmaceutical products in the United States (1). Although the FDA maintains a “list” of inactive ingredients, the EU and other European countries do not have official published lists, although steps are being taken to rectify this situation.

Few excipients are manufactured specifically for pharmaceutical use. Many are manufactured for other purposes (e.g., food, cosmetics, paint thickeners, construction, etc.). For their use in pharmaceuticals, additional quality, functionality, and safety requirements must be met.

Improper Use of Excipients

The improper use of excipients is addressed, to a certain extent, by the package inserts found in the formulated products. The challenge is to educate consumers and health providers to read and comply with the information contained in these inserts.

DEFINITION OF AN EXCIPIENT

For toxicological purposes, it may be inappropriate to define excipients as inert ingredients. It may be more appropriate to define an excipient (9) as “Any substance other than the active drug or pro-drug which has been appropriately evaluated for safety and is included in a drug delivery system to either:

1. Aid processing of the system during manufacture
2. Protect, support, or enhance stability, bioavailability
3. Assist in product identification
4. Enhance any other attribute of the overall safety and effectiveness of the drug product during storage and use.”

As the fourth definition indicates, excipients include a multiplicity of activities from mold releasers to absorption enhancers, and more recently include substances that permit large molecule (e.g., proteins) to be absorbed from the gastrointestinal tract without degradation. Most actions by an excipient are mechanical rather than pharmacological.

APPROVAL MECHANISMS FOR EXCIPIENTS

Currently, regulatory agencies have not established safety-testing guidelines specifically for excipients (10–13). Under U.S. law, a new pharmaceutical excipient, unlike an

active drug, has no regulatory status unless it can be qualified through one or more of the approval mechanisms available for components used in finished drug dosage forms. These approval mechanics include:

- Generally Recognized As Safe (GRAS) determination pursuant to 21 Code of Federal Regulations (CFR) 182, 184, and 186
- Approval of a food additive petition under 21 CFR 171
- As contained in a New Drug Application (NDA) approval for a specific drug product and for a particular function or use in that dosage form

Within the EU there is a directive that makes it clear that new chemical excipients will be treated in the same way as new actives (14).

TOXICITY TESTING

The very nature of excipients, for the most part, represents unique problems in testing for toxicity. The actions sought for many excipients are mechanical rather than physiological. Exceptions to this are flavors (12). A most desirable description of some excipients would include being pharmacologically inert and mechanically functional. An alternative would be one where the toxic dose was so high as to be meaningless while still retaining functionality requirements through a range of high and low doses. The acceptable risk for a traditional excipient, when compared to an active principle in a formulation, is generally several orders of magnitude different. Unless an excipient has some very unique properties, it is unlikely that a new excipient would be developed that did not have a large safety factor for toxicity and side effects under conditions of use.

As excipients become more complex and are required to perform functions not required in the past, it is conceivable that a distinction will have to be made between excipients and what might be termed “co-drugs.” The use of monoclonal antibodies to deliver an active principle to a specific tissue site might be considered an example of this diversity.

In 1994, as part of the IPEC-Americas program to obtain stand-alone status for excipients, a safety committee was formed. The committee was composed of men and women from a variety of medical and chemistry disciplines who were directed to develop safety-testing guidelines for new excipients. These guidelines were published in 1996 (12). At that time, regulations in most developed countries did not address registration of an excipient as a separate entity. For example, the drug

master file for an excipient in the United States is reviewed only as part of the NDA process. Inherent to the current process is the assumption that the use of an excipient in an approved drug dosage form ensures its acceptance in other dosage forms and its ultimate inclusion in the National Formulary (NF). The NF monographs provide standards/specifications for identity, purity, and analysis. Priority for inclusion is given to formulations with approved NDAs and those approved for use in foods. The FDA favors the use of commercially established excipients, such as food additives and substances that have been designated GRAS.

The guidelines developed by IPEC-Americas (12) provide for a tier approach to required testing. The tests to be conducted are based upon the route of application of the

formulated drug and the duration of use. A base set of data is required for all candidate excipients. The guidelines require a review of the chemical and physical properties of the excipient and a review of the scientific literature, exposure conditions (including dose, duration, frequency, route, and user population), and absence or presence of pharmacological activity.

Alternatives to the use of living animals are encouraged wherever these procedures have been validated. The information will provide sufficient information upon which to base a safety judgment and the data will be acceptable to a regulatory agency. The studies should also follow the appropriate legal and professional codes (15) in the conduct of all tests and should meet the Good

Table 1 Summary IPEC-America safety testing guidelines

Routes of exposure for humans:						
Tests	Oral	Mucosal transdermal/ injectable topical			Inhalation/ intranasal	Ocular
<i>Baseline toxicity data</i>						
Acute oral toxicity	R	R	R	R	R	R
Acute dermal tox.	R	R	R	R	R	R

^aAdditional assays are dependent on the judgment of the data evaluator. They may include, but are not limited to screening for endocrine modulators or tests to determine if findings in animals are relevant to humans.

(From Ref. 12, p. 53.)

Laboratory Practices of the agency-(ies) to which the data will be submitted.

The base set of data is designed to provide fundamental information regarding acute toxicity by the oral route and/or intended dose route (Table 1). Skin and eye irritation testing should be conducted irrespective of the route of use of the candidate excipient. These data are intended to protect researchers during the research and production life of the material.

Absorption/distribution/metabolism/excretion/pharmacodynamics are considered fundamental data, as are mutagenicity tests (e.g., Ames test, *in vivo* chromosome aberration test, and mouse micronucleus test). Twenty-eight day repeated dosing studies in two species by appropriate route(s) also should be performed in a rodent and a nonrodent species, respectively.

One of the unique aspects of the IPEC approach is that not all tests are required. Some of the tests are conditional upon findings in other test procedures. Specific attention is paid to the route of exposure as well as to tests that might be required as potential exposure duration is increased. Emphasis is placed on the fact that the route of exposure for the test animals should be the same as the route of exposure anticipated in humans. Strict attention is paid to the type of exposure. For example, a protocol for study of a product intended for inhalation therapy that results in prolonged exposure of up to several hours per day will differ from that used to evaluate a material that would be used in a product resulting in exposure to several metered doses each day. Some tests may have to be conducted using a route of exposure different from the intended use route. This may be due to the nature of the test animal (e.g., reproductive tests in rabbits may require that the dosage route be other than inhalation, if inhalation is to be the route of use of the formulation containing the excipient).

The IPEC-Americas publication emphasizes that untrained people should not use its guidelines. In addition, the guidelines are not to be used as a checklist. They are to be used by professionals qualified to make the necessary judgments concerning what is referred to as “Conditional” tests. The conduct of these conditional tests is dependent on the results obtained from other required tests. It was considered that given the specificity of some of the cellular and subcellular techniques available and the variety of test animals being developed, that the traditional long-term imprecise test procedures may produce irrelevant information compared to that available from other test procedures. Also, some chemical families produce false positive or questionable results in certain species and the development of these types of data only serve to confound and require additional testing to clarify the questionable results.

It is conceivable that some excipients may not require the standard 2-year, two rodent species carcinogenicity studies. Such excipients include those that are not absorbed (or are rapidly metabolized and/or rapidly excreted), that do not exhibit toxicity in 90-day studies, and those that are negative for genotoxicity. This is the approach taken by the IPEC-Americas Safety Committee and one of the reasons that the 1996 peer-reviewed journal publication (12) indicates that the conduct of rodent carcinogenicity studies is conditional. The carcinogenicity studies that are conditional are the traditional 50 animals/sex/group rodent studies conducted for 18 or 24 months or variations thereof. The decision to make these tests conditional was also predicated on the fact that other models, that provided adequate information upon which to base a safety judgment regarding carcinogenic potential, were available.

GENETICALLY ENGINEERED ANIMAL MODELS

The use of genetically engineered animals has the potential to supplant some of the traditional long-term (2-year) rodent studies. Mouse models have been developed for use as mechanistic models in cancer research. Potential alternatives to the 2-year rodent oncogenicity bioassay include the p53 knockout mouse and the Tg.AC mouse (16).

The use of these mouse models is based on the observation that human neoplasms commonly demonstrate molecular alterations in tumor suppressor genes and/or oncogenes. In normal tissues, tumor suppressor genes (such as p53 and Rb) serve as negative regulators of cell proliferation. Inactivation or loss of tumor suppressor activity through gene mutation or deletion results in loss of this critical regulatory function and may lead to uncontrolled cell proliferation.

Loss of tumor suppressor gene is the most common genetic alteration found in human cancers. Deletion of one or both alleles of p53 (p53 knockout mice) increases the incidence of neoplasia and decreases latency of tumor development. When p53 knockout mice are exposed to genotoxic agents, they rapidly develop neoplasms in a range of tissues. Sensitive targets in p53 mice are often comparable to those in “normal” mice and hence, their utility as a model.

The Tg.AC mouse is used as a skin tumorigenesis model, and when exposed to phorbol ester tumor promoters and other nongenotoxic agents, is rapidly induced. When fully validated, a test battery, including the

Table 2 Summary of IPEC-Europe excipient testing guidelines

Tests	Routes of exposure for humans:					
	Oral	Mucosal	Transdermal	Dermal/topical	Parenteral	Inhalation/intranasal
<i>Step 0</i>

(From the IPEC Europe Safety Committee. The Proposed Guidelines for the Safety Evaluation of New Excipients. European Pharmaceutical Review, Nov 1997.)

heterozygous p53 knockout mouse and the Tg.AC mouse, may provide a model which will identify both genotoxic and nongenotoxic carcinogens and reduce the in-life time to conduct studies for carcinogenicity to as little as 6 months.

SUMMARY

The tests suggested by IPEC-Americas are summarized in Table 1 (12). The “R” represents required tests and the “C” represents tests that are conditional based on intended use and the results of previous tests. The tests suggested by IPEC-Europe (18) are found in Table 2 and differ slightly from Table 1. The decision whether or not to perform “C” labeled tests requires the judgment of a trained professional. Both IPEC test models are also predicated on obtaining chemical, pharmacological, and physical data from other investigators involved in the development of candidate excipients. Information developed by chemists, pharmacologists, and other disciplines is invaluable in estimating the hazards associated with a new compound.

Testing in humans, using the IPEC-Americas model, either as part of a clinical trial or as a stand-alone procedure, should be conducted as soon as warranted by the animal data. Critical evaluation of the base- set data may support the use of a candidate excipient intended for use once or twice in a lifetime. If one conducts the studies listed in Table 1, section 2, critical evaluation of the data may support the use of the new excipient in a variety of products intended for limited repeated intake, for example an antibiotic. If the Absorption, Distribution, Metabolism, Excretion/Pharmacokinetics (ADME/PK) studies show that the excipient is not absorbed, review of the other data may permit inclusion in a product intended to be used for 30–90 consecutive days. For longer-term usage, the tests listed in Table 1, section 3 must be considered. One-generation reproduction studies must be conducted to assess any excipient-induced effects/disturbances in mating behavior, development/maturation of gametes, fertility, and preimplantation/implantation loss of embryos. Should the data continue to support some concern for either reproductive or developmental toxicity, a segment III study might be appropriate (3, 19, 20).

Specific details regarding test methodology are not provided in the guideline. Test procedures generally recognized by experts and the regulatory agencies should be used. Each test should be designed to address a specific issue and the data should be evaluated accordingly. Care

should be taken when evaluating animal data to ensure that toxicological findings are not unique to the particular test species and therefore not relevant to the human experience.

Finally, it is important that a material being evaluated for safety is the same as that which will be used in pharmaceutical preparations. The manufacturer of the excipient must follow GMPs. A complete audit trail must be available from the time of manufacture until the product is made available to the consumer. IPEC-Americas has developed a third-party audit program that follows the guidelines enumerated above. The program is conducted by the International Pharmaceutical Excipients Audits, Inc. (IPEA) and is the only program of its type that focuses only on the quality of pharmaceutical excipients. The program is designed to prevent problems with excipients, such as the one that occurred in Haiti in 1996, where 80 children died because the glycerol in their cough medication was mostly glycol.

Ultimately, the safety of an excipient in a formulation requires the following:

1. That the excipient being used is the same excipient that was tested for safety.
2. The test procedures were adequate to evaluate safety and are acceptable to relevant regulatory authorities.
3. The excipient is as specified.
4. The formulated pharmaceutical is used as specified.
5. The concentration of the excipient in the formulation takes into account appropriate test data.

EXCIPIENTS—POWDERS AND SOLID DOSAGE FORMS

Hak-Kim Chan
Nora Y.K. Chew

University of Sydney, Sydney, New South Wales, Australia

INTRODUCTION

Excipients are the additives used to convert pharmacologically active compounds into pharmaceutical dosage forms suitable for administration to patients (1). Although excipients are the nonactive ingredients, they are essential in the successful production of acceptable solid dosage forms such as tablets and powders. For example, the lack of filling materials would make it exceedingly challenging, if not impossible, to produce a 1 mg dose tablet of a potent drug.

The following general criteria are essential for excipients (2): physiological inertness; physical and chemical stability; conformance to regulatory agency requirements; no interference with drug bioavailability; absence of pathogenic microbial organisms; and commercially available at low cost.

In reality, no single excipient would satisfy all the criteria; therefore, a compromise of the different requirements has to be made. For example, although widely used in pharmaceutical tablet and capsule formulations as a diluent, lactose may not be suitable for patients who lack the intestinal enzyme lactase to break down the sugar, thus leading to the gastrointestinal tract symptoms such as cramps and diarrhea. The role of excipients varies substantially depending on the individual dosage form.

EXCIPIENTS IN TABLETS AND CAPSULES

For tablets and capsules, excipients are needed both for the facilitation of the tableting and capsule-filling process (e.g., glidants) and for the formulation (e.g., disintegrants). Except for diluents, which may be present in large quantity, the level of excipient use is usually limited to only a few percent and some lubricants will be required at <1%. Details of the types, uses, and mechanisms of action of various excipients for tablet and capsule production have been discussed at length in other articles

in this encyclopedia.^a The types and functions of excipients for tablet production are summarized in Table 1. Although binders, lubricants, and antiadherents are specific for making tablets, other excipients in Table 1 are also used in capsule production for reasons similar to those for tablets.

It is worth noting that some of these tableting excipients may exert effects in opposition to each other. For example, binders and lubricants, because of their respective bonding and waterproofing properties, may hinder the disintegration action of the disintegrants. In addition, some of these tableting excipients may possess >1 function that may be similar (e.g., talc as lubricant and glidant) or opposite (e.g., starch as binder and disintegrant) to each other. Furthermore, the sequence of adding the excipients during tablet production depends on the function of the excipient. Whereas the diluents and the binders are to be mixed with the active ingredient early on for making granules, disintegrants may be added before granulation (i.e., inside the granules), and/or during the lubrication step (i.e., outside the granules) before tablet compression.

EXCIPIENTS IN FREEZE-DRIED (LYOPHILIZED) POWDERS

Freeze-dried (lyophilized) powders are obtained by the process of freeze-drying (lyophilization), which involves freezing of an aqueous-based drug solution in a glass vial followed by sublimation of the ice in a vacuum (3). Because the process is carried out at low temperatures, it is most suitable for heat-sensitive compounds. Antibiotics, such as cephalosporins, are among the preparations commonly prepared by freeze-drying (4). An interesting finding of excipients in freeze-drying is related to breakage of the glass vial (5). This was observed in excipients, such as mannitol, which would undergo mechanical expansion during warming after fast freezing.

Excipients are used in freeze-drying for various purposes. They act as bulking agents to give a pleasing

Table 1 Summary of types and functions of tableting excipients

Excipient	Functions	Examples
Diluent	To act as a bulking agent or filling material	Sugars, lactose, mannitol, sorbitol, sucrose Inorganic salts, primarily calcium salts Polysaccharides, primarily microcrystalline celluloses
Binders and adhesives	To hold powders together to form granules for tableting	Sugars, glucose, syrup Polymers, natural gums, starch, gelatin or synthetic celluloses, polyvinylpyrrol-pyrrolidone (PVP), poly-methacrylate (Eudragit TM)
Glidants	To improve the flow of granules from the hopper to the die cavity to ensure uniform fill for each tablet	Fine silica, magnesium stearate, purified talc
Disintegrants	To facilitate the breakup of a tablet in the gastrointestinal tract	Starch and derivatives (polyplasdone XL) Microcrystalline cellulose
Lubricants	To reduce the friction between the granules and the die wall during compression and ejection of the tableting process	Clays, algin, gums, surfactants Water-insoluble: metal stearates, stearic acid, talc Water-soluble: boric acid, sodium chloride, benzoate and acetate, sodium or magnesium lauryl sulfate
Antiadherents	To minimize the problem of picking, i.e., portion of the tablet face picked out and adhered to the punch face during tableting	Carbowax 4000 or 6000 Talc, cornstarch, metal stearates, sodium lauryl sulfate
Colorants	For identification purposes and visual marketing values	Natural pigments Synthetic dyes
Flavors and sweeteners	To improve the taste of chewable tablets	Natural, e.g., mannitol Artificial, e.g., aspartame

appearance to the freeze-dried products. Buffers are present to control the pH of the products that are stable only within a narrow pH range in solution, both during freezing and the subsequent reconstitution. However, it is important to realize that certain buffers, such as the phosphate buffer, in which $\text{Na}_2\text{HPO}_4 \cdot \text{H}_2\text{O}$ crystallizes during freezing, cause a pronounced drop in pH (6). This can lead to deleterious effects on the active ingredients, according to the pH dependence of the product stability. Other excipients that may be present in freeze-dried powders include: solubility enhancers (e.g., surfactants or cosolvents), osmotic agents (e.g., saline and sugars), antioxidants (e.g., ascorbic acid), and preservatives for multiple-injection containers (e.g., benzyl alcohol and chlorobutanol). In addition, freeze-dried biological powders may also contain excipients that function to reduce protein adsorption onto the container surface (e.g., surfactants and albumins) (7). A particularly important

use of excipients for therapeutic protein formulations is the stabilization of the protein molecules in the dry state, as discussed later.

Therapeutic Protein Formulations

Therapeutic proteins are usually prepared in liquid formulations or as freeze-dried powders that are to be reconstituted immediately before use. A number of the proteins have been found to be unstable when dried alone, with aggregation being a major problem. It has been found that stability can be greatly improved if the proteins are dried in the presence of certain excipients (8, 9). However, not all excipients that can stabilize protein against aggregation are suitable. Other considerations required of the excipients for use in protein pharmaceuticals include:

Redox reaction potential: reducing sugars such as lactose and sucrose may not be suitable if they react with the protein (e.g., via the lysine residue) resulting in protein glycosylation [e.g., lactosylation of recombinant deoxyribonuclease I by lactose (10)] and other reaction products. However, glycosylation alone may not necessarily be a problem if the glycosylated proteins do not cause toxicity and immunogenicity while maintaining the therapeutic efficacy.

Parenteral use suitability: excipients such as trehalose, which has not been used in any products acceptable by regulatory authorities, may create concerns over toxicity.

Nonparenteral use feasibility: for example, inhalation drug delivery; lactose has been used for marketed aerosol products and hence may be more suitable for inhalation protein formulations.

Table 2 gives some examples of excipients used as stabilizers for proteins in freeze-dried formulations. Among others, saccharides are the most widely used excipients for stabilizing freeze-dried therapeutic proteins. There are exceptions to the need for stabilizing excipients, e.g., recombinant (α -Antitrypsin was stable when freeze-dried alone or with lactose, sucrose, and polyvinylpyrrolidone (11).

The mechanism of the protective effects imparted by the excipients has not been fully elucidated. Empirical observations have pointed to the following contributing factors: formation of a glassy state of the protein–excipient system; crystallinity of the excipients; hydrogen bonding between the excipient and protein molecules; and residual water content.

Glass is an amorphous or noncrystalline solid. It is characterized by the glass transition temperature above which the glassy state softens to the rubbery state. Protein stabilization imparted by excipients can be achieved when the freeze-dried powders are held below the glass transition temperature (T_g) of the protein–excipient systems (i.e., in the glassy state). Of particular relevance to the protein stability is that in the glassy state, the diffusion rate and mobility of the molecules are much less than those in the rubbery state. Thus, any physicochemical reactions leading to protein degradation will be diminished as the protein molecules are “frozen” in the glass formed by the excipients (12).

In contrast to the amorphous excipients, crystalline excipients, such as mannitol, were reported to reduce the stability of proteins (13). Mannitol can be used if the powder is rendered amorphous by the presence of other excipients such as glycine (14). Evidence for protein stabilization by hydrogen bonding has mainly come from

the Fourier transformed infrared (FTIR) spectroscopy (15), which provides information on the protein secondary structures. The amide I absorption band (approximately $1600\text{--}1700\text{ cm}^{-1}$) of freeze-dried proteins with excipients was found to bear more similarities than the freeze-dried proteins alone to the native proteins in the aqueous environment. This has been explained by sustenance of the native protein structures by protein–excipient hydrogen bonding in the dry powders. However, FTIR measurements were mostly carried out in compressed potassium bromide disks containing the protein. The integrity of the compressed proteins has been largely overlooked (16).

Water affects the stability of proteins by enhancing the mobility of the protein molecules (17). It has been established that an optimal level of water is required to maintain stability of proteins during storage (18). Moisture was known to increase the mobility of the surface groups of protein as measured by solid-state nuclear magnetic resonance spectroscopy (19, 20). The distribution of water between the protein and the excipients in a freeze-dried powder depends on the crystalline or amorphous nature of the excipients (21). For example, if a protein is formulated with an amorphous excipient and stored in a sealed container, water would distribute according to the water affinity of the protein and excipients (21). When the amorphous excipient crystallizes (e.g., because of elevated temperatures), it will expel its sorbed water, which may cause stability problems in the protein (8).

EXCIPIENTS IN POWDER AEROSOL FORMULATIONS

Pharmaceutical inhalation aerosols are widely used for treatment of diseases such as asthma and chronic bronchitis. There are three basic types of aerosol products: the propellant-driven metered-dose inhalers, the dry powder inhalers, and the nebulizers (33). Because of the ozone-depleting and greenhouse effects of the chlorofluorocarbon (CFC) propellants, interest in the dry powder aerosols has risen in recent years.

The main use of excipients in the dry powder inhaler formulations has been to act as carriers for the active ingredients (Table 3). The performance of a dry powder system depends on both the aerosol device and the powder formulation. To generate respirable aerosols, powder formulations must meet two opposing criteria: the particles have to be sufficiently fine (e.g., $<7\text{ }\mu\text{m}$) for lung deposition, and yet coarse enough for optimal flow in device (and capsule)-filling and emptying. To achieve this, the drug is blended with coarse inert excipient carriers (34).

Table 2 Some examples of excipients used as protectants for freeze-dried protein and peptide formulations

Protein	Excipients and uses	Reference
Recombinant human growth hormone (rhGH)	Mannitol and glycine as amorphous excipients to prevent human growth hormone (hGH) aggregation.	14
Bovine and human insulins	Trehalose as a lyoprotectant, reserves the secondary structure of rhGH.	22
	Dextrin, Emdex™ (spray-dried dextrose) and hydroxypropyl β-cyclodextrin minimized insulin aggregation	23
Recombinant factor IX	Polysorbate 80 as protectant for freezing; sucrose as protectant for drying; histidine as pH buffer; glycine for cake appearance	24
Recombinant human interleukin-6	Aggregation prevented by amorphous trehalose, sucrose or a combination of sucrose, and glycine or mannitol	25
Recombinant human interleukin-1 receptor antagonist	Sucrose, sorbitol, trehalose and alanine as protectants against aggregation and deamidation; mannitol and glycine as bulkingagent; sodium citrate as buffer	26
FK906 tripeptide	Sugars (sucrose, lactose, trehalose, maltose), polymer (dextran) and salts (NaCl, KCl) to modify the glass transition temperatures of the freeze-dried powders	27
Recombinant human albumin	Organic acid excipient molecules with either a carboxyl group or an amino group present at C-1 position completely stabilized rHA against aggregation	28
Lactate dehydrogenase	Polyethylene glycol as protectant for freezing; sugars (mannitol, lactose, trehalose) as lyoprotectants against loss of bioactivity	29
Alkaline phosphatase	Lactose and trehalose maintain activity longer at elevated temperatures than mannitol	30
Recombinant bovine somatotropin, lysozyme	Both the excipient type (sucrose, sorbitol, glycerol) and moisture content affected protein degradation	31
Hemoglobin	Mannitol protected protein from phase separation induced damage during freeze drying	32
Recombinant human factor XIII	Trehalose and sucrose preserved the native dimeric structure of the protein and prevented aggregates formation	

Table 3 Some examples of excipients used for dry powder aerosols

Active ingredient	Excipient carrier	Reference
Salbutamol sulfate	Lactose (63–90 μm): regular, spray-dried, and recrystallized	34
Budesonide	Lactose (α-monohydrate (<32 μm, 63–90 μm, 125–180 μm)	39
rhDNase	Lactose (50 wt% < 42 and 115 μm)	38
	Mannitol (50 wt% < 43 μm)	
	Sodium chloride (50 wt% < 87 μm)	
Bovine serum albumin–maltodextrin (50–50)	Lactose (α-monohydrate (63–90 μm)	40
	Fine particle lactose (76 wt% < 10 μm)	
	Micronized polyethylene glycol 6000 (97.5 wt% < 10 μm)	
Recombinant human granulocyte-colony stimulating factor-mannitol	Polyethylene glycol 8000 (38–75 μm, 90–125 μm)	41

Thus, the primary reason of using excipient carrier is to enhance flowability of the drug powder. The excipient carriers are large particles which, because of their sizes ($>50\text{ }\mu\text{m}$), would not be inhaled into the lung. They provide surfaces for the fine drug particles to adhere (Fig. 1), forming an interactive powder mix that would have an improved flowability than the drug alone for handling. On dispersion of the powder by air flow, the fine drug particles are detached from the carriers for inhalation. In an ideal drug-carrier system, the adhesion of the drug to the carriers is strong enough to prevent demixing during filling, handling, and storage, but not so strong as to prevent the generation of fine drug particles by detachment from the carrier during inhalation.

Another reason for using excipient carrier is to improve the availability of fine drug particles in the aerosol cloud. Surface texture of excipients appears to play a prominent role. The fine particle fraction of the antiasthmatic drug salbutamol sulfate was significantly higher with the recrystalline lactose as carrier than with regular or spray-dried lactose. The difference was attributed to the lower surface rugosity (roughness) of the recrystalline lactose (35). With another antiasthmatic compound, salmeterol xinofoate, a formulation using lactose carrier produced a higher fine particle fraction than formulations containing sucrose or spray-dried sorbitol (36). The implication is that using a suitable excipient as carrier it is possible to generate the desirable amount of fine drug particles in an aerosol with a minimal inspiratory effort. Recombinant human deoxyribonuclease I (rhDNase), the first therapeutic protein approved by the Food and Drug Administration (FDA) in the United States for inhalation use in the treatment of cystic fibrosis (37), generated a twofold increase in the fine particle fraction in the aerosol when blended with excipients lactose, mannitol, or sodium chloride (38). In this case, the increase was independent of both the type and relative amount of the excipient used.

Besides surface texture, excipient particle size also plays an important role in the fine particle generation as shown by budesonide, where the highest fine particle fraction was obtained with small-sized ($<32\text{ }\mu\text{m}$) lactose as the carrier (39). Additionally, fine particle excipients such as fine lactose or polyethylene glycol were reported to improve the performance of carrier-based protein dry powder aerosols (40). However, there are some cases where carriers improved total powder emission but reduced the percent of active powders in the aerosol (41). To be useful carriers, the excipients must be physically stable. The important physicochemical characteristics for drug carrier selection are discussed in Ref. 42.

Fig. 1 An example of excipient as carrier for drug particles. Scanning electron micrographs showing adhesion of recombinant human deoxyribonuclease I (rhDNase) particles to lactose (*top*) and mannitol (*bottom*).

In addition to being used as carrier, excipients can enhance the aerosol performance by cospray-drying with the active ingredient. In this case, instead of being external to the drug particles, the excipient exists with the active ingredient in the same particle. For example, using sodium chloride as a crystalline excipient, the fine particle fraction of rhDNase in the aerosol was increased linearly with the amount of excipient present (38). The enhancement was correlated with the degree of crystallinity of the powder in Fig. 2.

As pointed out at the beginning, excipients are not the active ingredients and should be physiologically inert. However, a special use of excipients in dry powder aerosols has been for bronchial provocation testing in asthmatics (43, 44) and for the enhancement of mucociliary clearance in both normal and asthmatic subjects (45, 46). In both cases they acted as the active

Fig. 2 Relationship between dispersibility (expressed as percent weight of particles less than 7 μm in the aerosol) and crystallinity (by X-ray powder diffraction) of rhDNase powders with different sodium chloride contents. (Adapted from Ref. 38.)

ingredients. The excipients are osmotic agents such as sodium chloride and mannitol. They change the osmolarity of the airway fluid, leading to the physiologic effects of enhanced clearance in the lungs or bronchoconstriction in hyperresponsive subjects.

EXCIPIENTS IN SPRAY-DRIED POWDERS

Spray-drying is a process where a drug solution is atomized to fine droplets followed by evaporation in a stream of warm air to form dry particles (47). The properties of the spray-dried products are controlled by both the process and formulation parameters (48). During the process, the active ingredients are subjected to mechanical shears from atomization and heat stress from the drying air at elevated temperature. Because of the tremendous surface area exposure of the atomized droplets, the drug will also be subjected to degradations such as oxidation and surface denaturation. Excipients can be used as stabilizers or protectants against degradation of the active ingredients. Autoxidation of the analgesic and anti-inflammatory agent aminopyrine was eliminated by excipients such as antioxidants, chelating agents, and clay (49, 50). Denaturation of the model protein (β -Galactosidase) was prevented in the presence of trehalose as an excipient (51). Sucrose was found to minimize the degradation product methemoglobin when oxyhemoglobin was spray-dried (52). Recombinant human growth hormone (rhGH), degraded by aggregation resulting from surface denaturation during spray-drying, was successfully stabilized by the

surfactant polysorbate 20 (53). Lactose has been found to protect spray-dried rhDNase against aggregation during storage (54, 55). As a cospray-dried excipient, sodium chloride was reported to increase the dispersibility of the spray-dried rhDNase powder to form aerosols for inhalation (38).

Excipients such as colloidal silica have been reported to increase the flow of spray-dried aminopyrine-barbital powders (49). In contrast, formulations of spray-dried salicylic-acid-containing gelatin and polyvinyl alcohol as excipients were less free-flowing (56). Gum arabic and polyvinylpyrrolidone prevented the sublimation of salicylic acid during spray-drying. For vitamin E acetate, the cospray-dried excipients affected both the powder flowability and drug release properties. Hydroxypropyl cellulose improved the drug release properties; AerosilTM (colloidal silica) enhanced the powder flow. A balance between these two physical parameters was achieved with approximately 6:1 weight ratio of cellulose to Aerosil (57).

Although it does not effectively protect ascorbic acid against oxidative degradation, colloidal silicon dioxide was found to increase the yield of spray-dried powder (58).

For polymorphic compounds, such as sulfa drugs, talc excipients induced polymorphic transformation of sulfamethoxazole during the process of microencapsulation by spray-drying (59).

Particle size and true density of spray-dried sodium salicylate were affected by binder excipients (56). Drug distribution in spray-dried tolbutamide particles was dependent on the disintegrant excipients used. The drug distributed throughout the particles with low-substituted hydroxypropyl cellulose as excipient but only deposited on the surface with pregelatinized corn starch (60).

Excipients like dibutyl phthalate were used as plasticizers for controlled-release microspheres of theophylline and sulfamethazine prepared by spray-drying (61). Likewise, citric acid was used as plasticizer for spray-dried sodium carboxymethyl cellulose and hydroxypropylmethyl cellulose microspheres containing theophylline (62). Excipients were found to affect the release rate of theophylline with citric acid and triethylene citrate giving the slowest and fastest rate, respectively, as compared with polyethylene glycol and glycerin excipients.

EXCIPIENTS IN CONTROLLED RELEASE SOLID DOSAGE FORMS

Polymeric excipients are commonly used for controlled-release formulations either as a coating around a drug core by microencapsulation or as a matrix in which the drug is

embedded. Depending on the release profile requirement, polymeric excipients are traditionally classified as hydrophilic or hydrophobic. Some representative coating materials include water-soluble resins (e.g., gelatin, starch, polyvinylpyrrolidone, water-soluble celluloses), water-insoluble resins (e.g., polymethacrylate, silicones, water-insoluble celluloses), waxes and lipids (e.g., paraffin, beeswax, stearic acid), enteric resins (e.g., shellac, cellulose acetate phthalate) (63). (Further details on polymers for controlled release systems can be found under “Biopolymers for Controlled Drug Delivery” in the first edition of this encyclopedia series.) Here the focus is on some recent applications of excipients in biologicals.

Live rotavirus vaccine was developed for oral delivery to prevent infections by the virus in young children (64). However, incorporation of live rotavirus into poly (DL-lactide-co-glycolide) microspheres or alginate microcapsules was reported to result in a significant loss of rotavirus infectivity. The loss was reduced by stabilization of the rotavirus vaccine with an excipient blend of cellulose, starch, sucrose, and gelatin at a mass ratio of 30:30:30:10 in granules or tablets (64).

Transforming growth factor (TGF)- β 1, a cytoprotectant against the toxicity caused by cell cycle-specific drugs, was encapsulated in alginate beads as a potential oral delivery system to release TGF- β 1 in the gastrointestinal tract. However, the TGF- β 1 was interacting with alginate, which prevented the release of the protein. Polyacrylic acid, as a polyanion excipient, was used to shield the TGF- β 1 from interacting with the alginate (65).

Glucose at concentrations >10% was used to achieve adequate reconstitution of freeze-dried biodegradable poly-DL-lactide nanoparticles with conservation of the encapsulated cyclosporin A (66). Glucose and trehalose were also found to be the most efficient cryoprotectors for the lyophilization process, whereas trehalose was used for spray-drying, in the production of solid lipid nanoparticles (67).

Tetanus toxoid (the vaccine for tetanus) encapsulated in polyester microspheres was produced for single-injection immunization (68, 69). The entrapment efficiency of the protein vaccine was significantly improved by coencapsulation with excipients such as trehalose and (γ -Hydroxypropyl) cyclodextrin. However, these excipients did not impart stabilizing effect on tetanus toxoid. In contrast, bovine serum albumin was found to be the most prominent stabilizer for protein in the body after administration by injection.

It is important to point out that the stabilizing effects of excipients were sometimes reported for the formulations in vitro rather than in the in vivo conditions. However, the

degree of retention of the native protein structure in the dry state may not be a general indication of stability for the ‘wetted’ solid within polymer controlled-release devices in the body. In the case of tetanus toxoid, it was shown that the extent of structural alternations in the presence of 1:5 (gram excipient:gram protein) sodium chloride, sorbitol, or polyethylene glycol did not correlate with stability conferred toward moisture-induced aggregation (70).

Surfactant and polyethylene glycols (PEG) excipients have been used in microencapsulation of macromolecules for various effects. For example, Tween 20, at the critical micelle concentration and at a molar concentration of protein:surfactant of 1:0.018 or larger, was found to increase the encapsulation efficiency of β -Lactoglobulin in poly (DL-Lactide-co-glycolide) microspheres (71). The initial burst release was reduced with increasing Tween 20 concentration, and the effect was attributed to reduction of the number of pores and channels inside the microspheres. For gene therapy, the release of biologicals encapsulated in microspheres can be significantly improved by adding surfactant during microencapsulation, as recently exemplified by the enhancing effect of polyvinyl alcohol on the release of adenovirus from PLGA microspheres (72). PEG 400 has been used to improve the stability of the protein, nerve growth factor (NGF) during the microencapsulation by a double emulsion method. It stabilized the protein by reducing the contact with the organic solvent in the process. Furthermore, the presence of NaCl in the microencapsulation process has been shown to modify the microsphere structures, leading to a reduction of the initial release rate of NGF (73).

EXCIPIENTS AND FORMULATION INCOMPATIBILITY

During formulation design some excipients may be incompatible with the active ingredient or with other excipients. Excipient incompatibility problems are, in fact, widely published and date back to the mid-1950s. For example, as a tableting excipient, lactose could react via its aldehyde group with both primary (1) and secondary (74) amines by the Maillard-type condensation reaction. Sorbitol, another excipient sugar, is hygroscopic at relative humidity >65%, which should thus be avoided during manufacturing. Calcium salts are other widely used tableting excipients. However, calcium carbonate is incompatible with acids or acidic drugs because of the acid–base chemical reaction. Calcium salts are also incompatible with tetracyclines because of the formation

of calcium–tetracycline complexes. Details of reactivities and incompatibilities of individual excipients are given in Ref. 1. Incompatibility attributable to excipients is commonly studied under accelerated testing conditions or using thermal analyses such as differential scanning calorimetry. However, the results of this rapid testing could be misleading and thus of very limited value (75).

Besides direct excipient–drug interactions, excipients can lead to instability of the active ingredient by an indirect role through moisture distribution. Residual water content is known to affect the stability of solid dosage forms and powders (76). Decomposition of cephalothin sodium and benzylpenicillin potassium decomposition in freeze-dried preparation was believed to be partly attributed to the effect of water binding to excipients (4). The degradation rate of cephalothin sodium increased with the water content of excipients corn starch and celluloses (77). The results were correlated with the water mobility in the presence of the excipients (4, 77). A study of the effect of various excipients on the solid-state crystal transformation of the antimalarial compound mefloquine hydrochloride revealed that microcrystalline cellulose promoted the transformation from form E into form D (78). However, methylcellulose, hydroxyethylcellulose, β -Cyclodextrin, cospovidone, and hydrous lactose had no effect. The effect was again explained by the difference in the water uptake behavior by the excipients. Aspirin was formulated with a sugar diluent containing approximately 8% moisture, which did not cause instability problems (79). This was ascribed to the moisture present in the formulation being unavailable to react with the aspirin. The availability of moisture associated with excipients in a formulation can thus be manipulated to control the hydration rate of the active ingredient as in the case of nitrofurantoin, with crystalline lactose giving the fastest and microcrystalline cellulose giving the slowest rate (80). The rate of hydrolysis of methylprednisolone sodium succinate was higher when cofreeze-dried with mannitol than with lactose (81). This correlated with the rate of crystallization of mannitol in the formulation and its subsequent effect on the water distribution in the solid. The stabilizing potency of excipients on recombinant human albumin against aggregation also correlated with the water-sorbing capacity of the excipients (27).

Instability attributable to excipient-mediated water distribution in solids and powders has been explained by excipient physical properties (21, 82–84). Crystalline materials will not uptake moisture until the deliquescent point is reached. In contrast, amorphous excipients will absorb water until their glass transition temperatures fall below the ambient temperature when the mobility of the molecules has increased so much that excipient

crystallization will occur to expel the absorbed water from the crystal lattice. Before crystallization, these excipient materials will act as buffers or sorbents to hold the excess moisture which, depending on the water activity, may not be accessible to the active ingredient that is thus be protected from moisture-mediated decomposition. However, when excipient crystallization occurs, the expelled water will become available to react, leading to instability of the drug.

CONCLUSION

Although excipients are the nonactive ingredients, they are indispensable for the successful production of acceptable solid dosage forms. The important roles played by excipients in tablets and capsules, freeze-dried, and spray-dried powders, as well as powder aerosol formulations, were discussed. Some recent applications of excipients in controlled, release formulations for biologicals were also highlighted. Finally, incompatibility problems attributable to excipients were considered with an emphasis on the indirect role of excipients through moisture distribution.

Fluid Bed Processes for Forming Functional Particles

Yoshinobu Fukumori

Hideki Ichikawa

Kobe Gakuin University, Kobe, Hyogo, Japan

INTRODUCTION

Fluid bed processors have been used for drying, agglomeration, and coating. In addition to a simple fluid bed, the tumbling, agitating, centrifugal, and spiral flow fluid bed and the spouted bed with or without the draft tube have been developed for improving the process performance. Agglomerates produced from the simple fluid bed process are usually characterized with their soft, porous properties. This is advantageous in their application to tableting because the easy deformation of the agglomerates leads to the hardening of the tablets. The fluid bed processes are also favorably applied to the coating of the pharmaceutical particles including the agglomerates and crystals. Among the many types of surface modification processes, the fluid bed processes are characterized with their easy, simple mechanical formation of multilayers on the particles. This has been producing many types of functional pharmaceutical particulate system for the purpose of efficient drug delivery, including the enteric-coated particles and the sustained, prolonged, and delayed release systems.

These agglomeration and coating technologies, which are established and well experienced in the pharmaceutical area, have been extended to other areas such as food and agricultural industries. However, the current fluidization technology has a limit in the size of the particles that can be processed.^[1] The extension of the size limit to a smaller range will lead to the wider applications. From practical aspects, the fluidized bed processes will be described below.

FLUID BED PROCESSORS

Typical fluid bed processors are illustrated in Fig. 1. Fig. 1A is a simple fluid bed, usually with a conical shape at the bottom of the chamber, leading to inducing spouted particle flow more or less depending on the angle of the conical chamber. The spray is supplied from the top toward the fluidized bed in agglomeration and into the bed in a tangential direction in coating. Elutriated particles from the fluid bed are trapped mostly by the bag filter and are returned to the bed by periodical shaking of the bag filter with or without a pause of fluidization air input and

spray in the agglomeration, but always without a pause in the coating. Fig. 1B is an example of the tumbling fluid bed processors. A typical construction of the tumbling fluid bed processor automatically operated is shown in Fig. 2. The fluidization air is supplied through the slit between the turntable and the chamber. The tumbling forces the particles to be centrifuged toward the chamber wall; then, the particles are blown up by the slit air. These make a circulating fluidized bed, in which the spray is supplied by the top or the tangential mode. The rolling of the particles on the turntable makes the wet particles roundish and compact. Fig. 1C is a typical assembly of the Wurster process, a kind of a spouted bed process assisted with a draft tube. The particles fluidized in the annular part between the draft tube and the chamber are introduced into the draft tube because of the accelerated airflow from the bottom and are then spouted from the draft tube. The particle velocity is reduced in the upper expansion chamber, leading to the return of the particles to the fluid bed in the annular part. During this circulating particle flow, the particles are sprayed in the draft tube; at the same time, they have a chance to be exposed to the spray air jet, which can exert a strong separation force to the particles. Usually, the particles are easily agglomerated or coagulated during spraying, but the above strong air jet can make the particles disintegrated. These characteristics of the Wurster process make it possible for the coating of the finer particles^[2] or for the production of the finer agglomerates for the purpose of agglomeration^[3] compared with the other type of the fluid bed processes.

The types of fluidization, as proposed by Geldart,^[4] depend on the particle size and density. Because the particle density of the pharmaceutical powders is mostly around 1.5 g/cm³, the particles are categorized into larger than 900 μm (D type), 900–150 μm (B type), 150–20 μm (A type), and smaller than 20 μm (C type) particles in the Geldart's fluidization map. The A and C types are cohesive and adhesive; therefore they are agglomerated into the D and B types to achieve free-flowing properties. This is the main purpose of agglomeration. The D type cannot be fluidized because of too large particle size; therefore the coating is simply processed using a rotating pan. The B type always exhibits bubbling fluidization which induces inhomogeneous particle flow; this is practically

Fig. 1 Schematic drawing of the typical fluid bed processors.

disadvantageous because such a flow especially in the spray zone leads to poor coating performance in the yield and homogeneity of the product. In order to achieve a homogeneous particle flow of the B-typed particles, particle flow patterns, different from the simple fluidization such as those in the tumbling, centrifugal, and spiral fluid

bed and the spouted bed, have been required. This is the reason why many different types of the fluid bed processor have been developed so far. The A-typed particles can be fluidized homogeneously without air bubbles, but the separation force from fluidization is not sufficient to avoid agglomeration. This prevents the fluid bed coating

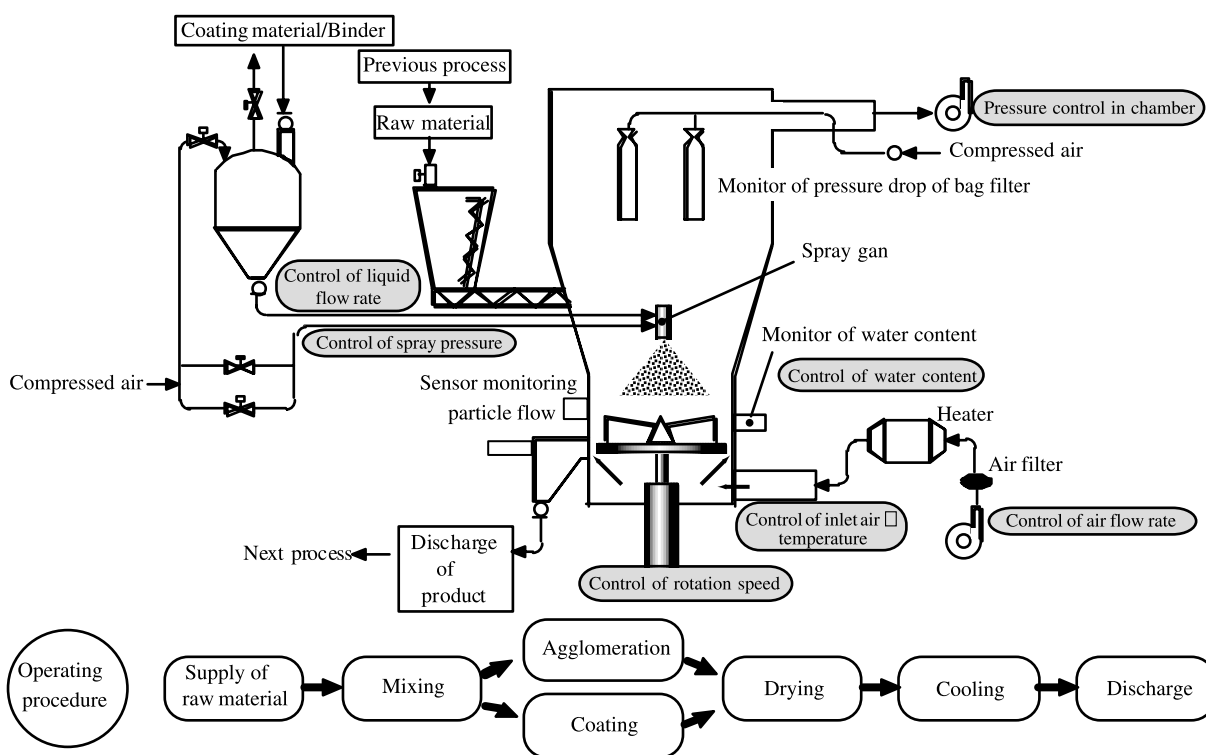

Fig. 2 Tumbling fluid bed processor (Agglomaster, Hosokawa Micron Corp.) operated automatically.

process from being industrially applied to these small particles despite many researches attempting the fine particle-coating technologies. The type C particles cannot be fluidized because of their small size.

When the particles are fluidized or spouted under spraying, separation force is exerted to the particles more or less agglomerated by the spray solution. Balance of the

separation force and the binding strength of the binder or coating material determines the degree of agglomeration, i.e., agglomerate size.^[5,6] Each fluid bed processor can generate its inherent separation force, surely depending on the operating conditions such as the airflow pattern and the inlet airflow rate. The excessive separation force can even disintegrate the core particles. Thus, depending on

the requisite of the final agglomerate size or the core particle size to be discretely coated, the optimal processor should be selected in practice.

MATERIALS FOR AGGLOMERATION AND COATING

Table 1 lists the typical binders and the coating materials for agglomeration and coating. The water-soluble polymers are used as a binder in agglomeration, and some of them are also used as a coating material. As each type of the water-soluble polymers becomes higher in molecular weight, it contributes more to the increase in the viscosity of its solution and the interparticle binding strength, leading to more enhanced particle growth in agglomeration and coating.^[5,6]

The commercially available polymeric dispersions, which have been most widely used as a coating material, are classified into three types based on the preparation methods:^[7] 1) latexes synthesized by emulsion polymerization; 2) pseudolatexes prepared by emulsion processes such as emulsion solvent evaporation, phase inversion, and solvent change; and 3) dispersions of micronized polymeric powders.

Eudragit L30D and NE30D are acrylic copolymer latexes synthesized by emulsion polymerization.^[8] The

particle sizes of these latexes are in submicron order. L30D is a copolymer of ethyl acrylate (EA) as an ester component with methacrylic acid (MA) (MA/EA 1:1). It is used for enteric coating because of the presence of carboxyl groups in the copolymer. NE30D is a copolymer of ester components only, EA and MMA (2:1). The films formed from NE30D have a very low softening temperature and hence are flexible and expandable even under indoor conditions.

Cellulose derivatives cannot be synthesized directly in the latexes; therefore they are prepared as pseudolatexes (Aquacoat, Aquateric,^[9] and Surelease^[10]) or micronized powders [Acoat hydroxypropylmethylcellulose acetate succinate (HPMCAS)^[11] and EC N-10F]. While the pseudolatexes can be prepared as submicron particles, the micronized powders have mean particle sizes of a few micrometers. Poly vinyl acetate phthalate (VAP) is also supplied as a micronized powder (Coateric).^[10] Eudragit RS and RL are terpolymers of EA and MMA as ester components with trimethylammonioethyl methacrylate chloride (TAMCl) as hydrophilic quaternary ammonium groups; RS and RL are 1:2:0.1 and 1:2:0.2 terpoly(EA/MMA/TAMCl), respectively. Because Eudragit RS and RL contain MMA-rich ester components (EA/MMA 1:2), they have softening temperatures higher than those of NE30D (EA/MMA 2:1) and form hard films under indoor conditions. Eudragit RS and RL powders are easily trans-

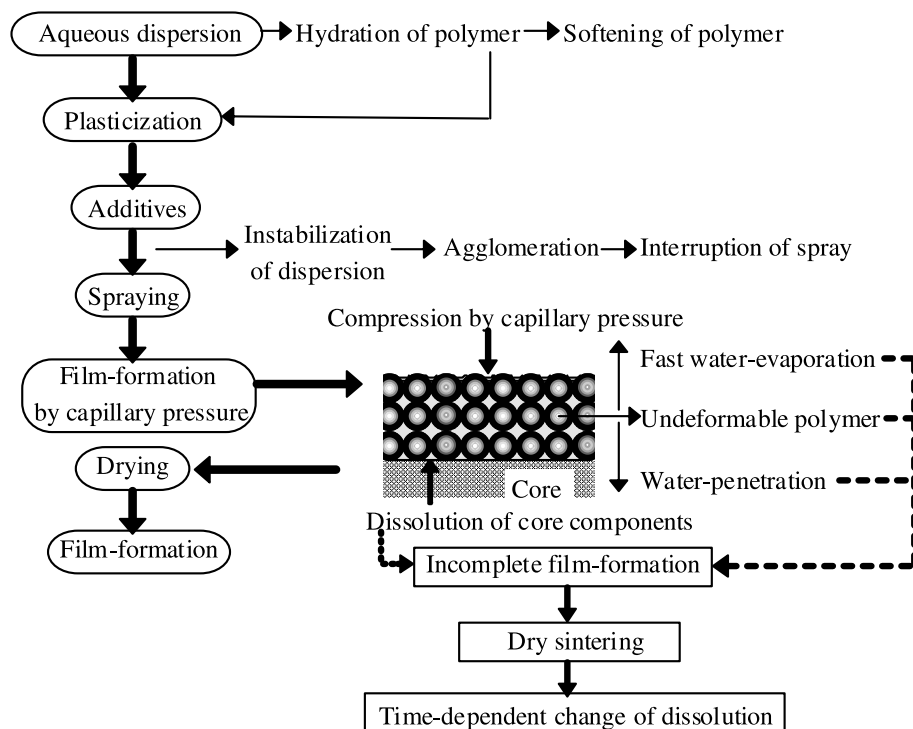

Fig. 3 Film formation from the aqueous polymeric dispersions.

Fig. 4 Structure of agglomerates.

formed into pseudolatexes by emulsifying their powders in hot water without additives.^[8] It is costly to ship the aqueous dispersions around the world; therefore the Aquateric pseudolatex is supplied as a spray-dried powder. It is redispersed just before use.^[9]

A variety of additives are incorporated into the dispersions as surfactants (Tween 80, sodium lauryl sulfate, polyoxyethylene nonyl phenyl ether, cetyl alcohol, and Pluronic F-68), plasticizers (dibutyl sebacate, oleic acid, and Myvacet 9-40), pigments, anti-adherents (fumed silica), anticoagulant (Myvacet 9-40), preservatives (sorbic acid), and stabilizers (ammonia).^[7]

The film formation process from the aqueous dispersion is shown schematically in Fig. 3. The mechanisms of film formation from the aqueous polymeric dispersions have been discussed for a long time, and many theories have been proposed. The detail was reviewed by Muroi^[12] from a basic point of view. Film forma-

tion in pharmaceutical applications was discussed by Lehmann,^[8] Steuernagel,^[9] and Fukumori.^[7] Fusion and film formation of the polymeric particles during the coating process can be explained by the wet sintering theory for particles suspended in water, the capillary pressure theory for particle layers containing water in various degrees of saturation, and the dry sintering theory for dry particle layers.

PARTICULATE DESIGN AND PREPARATION

The typical particle structures produced from the agglomeration process are shown in Fig. 4. Simple agglomerates (Fig. 4A) are prepared by fine drug powder(s) being mixed with fine powders of additives in the fluid bed, and then binder solution being sprayed from the top in the simple fluid bed (Fig. 1A) followed by drying. In this case, because the particles are agglomerated in the fluidization airflow, they are usually very porous. The tumbling fluid bed or the spouted bed process assisted with draft tube (Fig. 1B and C) can be applied if more compact agglomerates are required. When fine drug powder is agglomerated with the coarse carrier particles (cores in Table 1), drug-layered agglomerates shown in Fig. 4B can be prepared.^[13] In the latter process, the tumbling fluid bed is often used because tumbling on the turntable contributes to the efficient layering of the fine powder. The drug-layered agglomerates are often used as core particles in the coating process.

Among the many kinds of the surface modification process, the fluid bed processes can most easily produce multilayered particle structure with each layer being monolithic, random multiphase structure, ordered multiphase structure, and so on (Fig. 5). The combination of

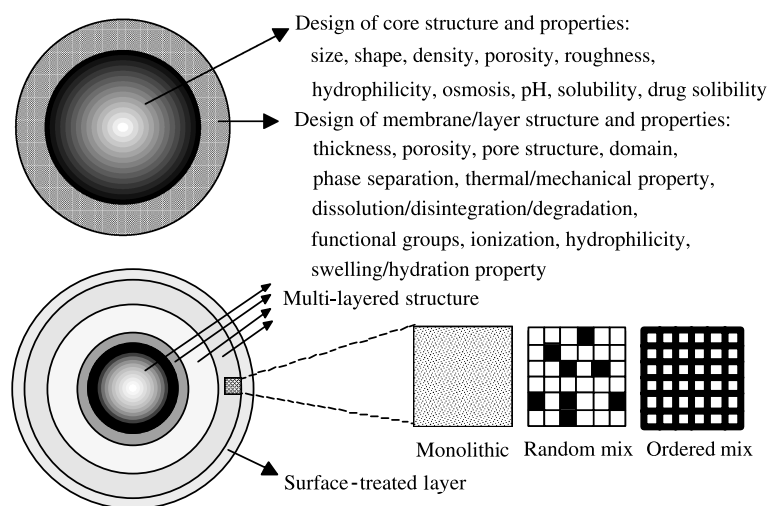

Fig. 5 Particulate structures produced by the fluid bed process.

Fig. 6 Schematic diagram of the structure of the particle for positively thermosensitive release of drug utilizing gel-collapsing behavior of poly(*N*-isopropylacrylamide).

the different components and layers can produce almost infinite types of functional particles. As an example, designs and preparations of several thermosensitive controlled-release particles will be described below.

Controlled-release technology based on the external temperature-activated release can find application in diverse industrial fields.^[1,14–16] In the pharmaceutical area, for example, the deviation of the body temperature from the normal temperature (37°C) in the physiological presence of the pathogens or pyrogens can be utilized as a useful stimulus that induces the release of the therapeutic agents from a thermosensitive controlled-release system. Physically controlled temperature using a heat source such as the microwaves from outside the body can also be used for temperature-activated antitumor drug release combined with the local hyperthermic treatment of cancer.

The membranes of the thermosensitive controlled-release microcapsules were constructed by a random mixing Aquacoat (Table 1) with the latex particles having poly(EA/MMA/2-hydroxyethyl methacrylate) core and poly(*N*-isopropylacrylamide (NIPAAm)) shell. This is an example where the membrane has the random two-phase structure as shown in Fig. 5. The microcapsules exhibited a thermosensitive release of water-soluble drug.^[17] The mechanism is explained in Fig. 6. When the temperature was changed in a stepwise manner between 30 and 50°C, the microcapsules showed an “on–off” pulsatile release. This “on–off” response was reversible.

Alternatively, this type of thermosensitive microcapsule can be prepared even with already established pharmaceutical ingredients. As is well known, hydroxypropyl cellulose (HPC), the commonly used binder and coating substrate (Table 1), has a lower critical solution temperature (LCST) around 44°C, and its water solubility dras-

tically changes across the LCST. Negatively thermosensitive drug release microcapsules with an HPC layer were thus designed by utilizing the thermally reversible dissolution/precipitation process resulting from the LCST phenomena^[18] (Fig. 7). This is the case that the particles are constructed with multilayers of monolithic structure (Fig. 5). The release rate from the microcapsules with sandwiched HPC layer was found to be drastically decreased when the temperature came near the LCST: the release rate at 50°C was approximately 10 times lower than that at 30°C. In contrast, no negatively thermosensitive release was obtained in the microcapsules without the outer coat of ethyl cellulose: the drug release rate was monotonously increased as the temperature increased.

Unlike many types of the millisized devices that have been developed so far, the microparticles mentioned here were around 100 µm in diameter, and the estimated membrane thickness was only several tens of microns. Such small dimensions of the thermosensitive materials incorporated into the microcapsule membranes provided a

Fig. 7 Particle exhibiting negatively thermosensitive drug release.

sharp release rate change in response to the temperature change. This may be one of the advantages of the fine particle-coating technology. The above-demonstrated flexibility in designing the membrane structures also offers considerable advantages over conventional microencapsulation methods.

CONCLUSION

Using the fluid bed processes and processors along with the appropriate materials and their well-designed formulation and particulate structure make it possible to prepare highly functional particles as demonstrated here. However, this method has an unavoidable limit in the size of particles that can be efficiently processed because a steady circulation or fluidization of the particles smaller than 20 μm is still difficult. In order to expand the applications of this process, some new or improved fluidization technologies will be required.

FLOW PROPERTIES OF SOLIDS

Stephen A. Howard

Purdue Pharma L.P., Ardsley, New York

INTRODUCTION

The preparation of essentially all dosage forms involves the handling of solid materials. Among all finished products, solid dosage forms are the most predominant in terms of volume and value. The importance of solid-handling properties, especially flow properties, cannot not be overemphasized. The flow properties of solids have great impact on the tableting and encapsulation processes since these dosage form manufacturing processes require the flow of powder materials from a storage container to filling stations, such as tablet dies or capsule fillers. Weight uniformity of course is dependent on the uniform and rapid flow of powders. The flow properties of solids also have great influence on the mixing and demixing of powders that take place before tableting or encapsulation. As is pointed out by Von Behren (1) in process steps affected by the flowability of formulations include mix uniformity and flow and of course the weight and pressure settings used. It should also be pointed out that the speed of production is also greatly affected by the formulation's flow characteristics. For the final product, Von Behren (1) lists, weight, content uniformity, hardness and disintegration/dissolution as being affected by formulation flow.

Different flow properties are required at different stages of processing and should be carefully taken into consideration during formulation and process validation. Kinetics of mixing is influenced by the physical state of the active constituent (2). Particle size of excipients has a significant effect on the content uniformity of ethinyl estradiol powder mixes and tablets. As the particle sizes of excipients increase, the degree of mixing decreases. The more free-flowing the excipient, the more abrasive the particle, facilitating the breakdown of drug agglomerates (3). On the other hand, segregation studies carried out in a two-dimensional segregation cell suggest that materials with good flow show demixing tendencies, whereas powder blends with poor flow are less apt to separate (4). Fast flow is not always helpful in weight uniformity of the finished product. Hauer et al. (5) showed that none cohesive free flowing powders gave poorer capsule fill uniformity since they were less cohesive and flowed out of

the dosators. Knowing your process and determining the characteristics needed to optimize that process is critical.

Characterization of powders is essential to quality control of raw materials, active or excipient, in order to maintain product uniformity. Flow-property studies of powder materials facilitate the scientific design of formulations and processing equipment, such as the design of mass-flow hoppers. This article reviews the flow properties of powder materials. The factors affecting the flow properties of solids are briefly discussed first, followed by measurement of flow properties.

FACTORS INFLUENCING THE FLOW OF SOLIDS

Nature of Powders and Granulations

Powders are generally considered as two-phase assemblies of discrete particles with interactions between gas and solid internal surfaces. A material is classified as a powder if it is composed of dry, discrete particles with a maximum dimension of less than 1000 μm according to British Standard 2955 (6). Powders differ from other physical states of matter since they are nonhomogenous in nature but consist of discrete solid particles of different sizes and shapes interdispersed with a gaseous phase. Powders are similar to solids in that they can exhibit both elastic recovery and brittle fracture. Unlike solids, however, powders can expand or contract when stressed. Preconditioning can change the nature of the material. The condition and duration preconditioning forces are applied to a powder can determine if and how a powder will flow. Under stress, powders can flow like a liquid. However, unlike liquids, they do not flow if the stresses are too small. When powder materials do flow, the stresses are not dependent on the rate of flow as they are with a liquid. In order to characterize the properties of an assembly of particles or a bulk mass, the collective properties of constituent particles within their gaseous environment must be determined. The solid-handling properties of a bulk mass are influenced by any factor that can have an effect on the particle-particle interactions of constituent particles. Factors associated with the nature of the particles

and their surfaces such as size, shape, surface morphology, packing conditions, and interparticle forces must therefore be considered. To make the situation more complex, the interparticle forces can be of a number of types: mechanical forces, surface tension, electrostatic forces, van der Waals forces, solid-bridge forces, or plastic welding forces; none of these can be readily quantified. The properties and phenomena associated with an assembly of particles are (7):

- Particle size distribution and specific surface area;
- Particle shape distribution;
- Cohesion, strength, and adhesion;
- Packing properties (bulk density, porosity);
- Rate and compressibility of packing;
- Flowability and failure properties;
- Segregation; and
- Angle of internal friction. A combination of these properties determines the behavior of bulk material.

Particle Size and Size Distribution

All matter interacts. As the dimensions of particles increase and the particles change in nature, the forces acting on them change. Fine powder particles less than 100 μm in diameter are acted upon primarily by surface forces. Particles above 1000 μm in diameter are governed by gravitational forces. Therefore, the balance of interaction forces determines powder behavior. With relatively small particles, the flow through an orifice may be restricted because the cohesive forces between the particles are of the same magnitude as gravitational forces. Since the latter forces are a function of the diameter raised to the third power, they become more significant as the particle size increases and flow is facilitated. Too large a particle however with respect to the orifice through which it has to flow can cause arching that can block flow from hopper or into a die or capsule dosator. The properties of solids that determine the magnitude of particle–particle interactions have been reviewed (8, 9).

In general larger particle flow faster than smaller particles. In the TSI Aero-Flow brochure (10) two sieved fractions of lactose, one larger than 38 μm and one less than 38 μm , were compared to the unfractionated lactose. As expected the fine fraction showed the poorest flow while the larger fraction showed the best flow characteristics in the Aero-Flow rotating drum tester while the unfractionated sample was between the two extremes. With wider particle distributions and gravimetric test methods such as flow from a hopper, density differences can be a determining factor until the cohesive nature of the fine particles decrease flow. Particle size and size

distribution has been systematically investigated for their effects on flow using a flat-bottom flowmeter (11). Increase in the content of fines increases the flow rate to a maximum value, followed by a decrease in flow rate if the content of fines is further increased. For a given concentration of fines, the flow rate increases to a maximum as the diameter of the fines decreases to approximately 90 μm ; further reduction in fine diameter reduces the flow rates. Equations of the Brown–Richards type relationship are adequate for modeling the static flow in such systems. Equation (1) relates the flow rate Q to powder density ρt and circular aperture diameter D_A :

$$D_A K [4Q/60\pi \cdot \rho t \cdot \sqrt{g}]^{1/n} \quad (1)$$

where K and n are material-dependent constants and g is the gravitational force.

In a similar study of the factors influencing the flow of lactose granules, a strong negative correlation was found between the flow rate of granules and proportion of particles less than 150 μm (100 mesh) in size (12).

A decrease in particular size of salicylic acid resulted in a decrease in the angle of internal flow Ψ , which was derived empirically as a measure of cohesiveness (13). The value of Ψ was found to be dependent on the relative proportion and particle size of salicylic acid and lactose when blends of these powders were studied. Geoffroy and Carstensen (14) have used shear cell measurements of sodium chloride, granular dicalcium phosphate (DiTab) and hydroxyapatite (TriTab) to examine the affect particle size has on the constants in the shear cell. They modified the Warren–Springs equation (Eq. 5 found in the Shear Cell section of this article) which relates cohesion and tensile strength of cohesive powders. They showed that cohesion stress (C) is related to tangential force (T) by the equation $C = \alpha T^\beta$ where α and β are constants dependent on the materials used. They also demonstrated relationship of α to particle diameter. They incorporated this into the Warren–Springs equation so that particle size could be better accounted for in analyzing shear cell data.

Shape Factors and Surface Morphology

Particle sizes combined with shape factors have been the subject of many of the recent studies regarding flow of solids. Sphericity, circularity, surface-shape coefficient, volume-shape coefficient, and surface-volume-shape coefficient are some of the most commonly used shape factors. It is generally accepted that the flowability of powders decreases as the shapes of particles become more irregular. Efforts to relate various shape factors to powder

bulk behavior have become more successful recently, primarily because of the fact that shape characterization techniques and methods for physically sorting particles of different shapes are improving. This is primarily thanks to the use of fractal geometry.

Fractal geometry was developed by B.B. Mandelbrot and was most fully described in a 1983 text (15). Fractal geometry essentially describes the space filling ability of a rugged line or surface by adding a fractional number to the to the topological dimension of a system as illustrated in Fig. 1. Brian Kaye and co-workers have extended Mandelbrot's concepts to describe the structure of rugged shaped powder grains and later to the distribution function of a powder (16–19). The use of fractal geometry and chaos theory has been used to develop a test method, using a rotating drum (10, 18, 19) and this test method will be described later in the article.

Hickey and Concessio (20) studied a series of powders of pharmaceutical interest using a vibrating spatula. In all

of the powders studied, mass flow rates increased as the particle size increased. Sodium chloride, which did not exhibit fractal behavior (very low fractal number), showed no irregular flow patterns. Lactose, cromolyn sodium and charcoal that did exhibit fractal behavior at low stride lengths, demonstrated irregular flow patterns. Kaye in unpublished data described the avalanching behavior of five lactose powders. Though similar in particle size, the various lactose samples showed different morphology and different avalanche behavior. Brittain (21) tested anhydrous and fast flow lactose, using Carr index and showed that the Fast-Flo lactose yielded higher flow capacity. He attributed this to the morphology of the two materials and the rounded edges in the Fast-Flo material. Cartillier and Tawashi (22) also related the flow properties and packing characteristics of seven different lactose powders as measured by the angle of repose and flow through an orifice to particle morphology, especially micro morphology as determined through a scanning electron

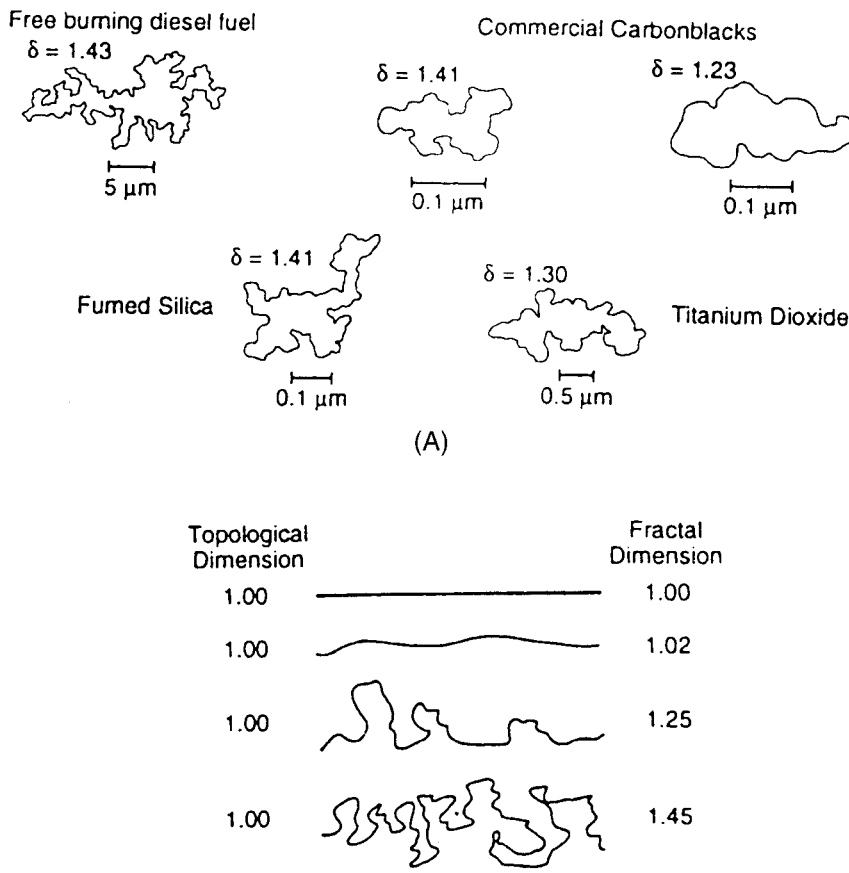

Fig. 1 (A) Profiles of fumed pigment fine particles where the fractal dimension, δ , describes the ruggedness of the profile. (B) Four lines with identical topological dimensions with varying degrees of ruggedness as seen from their corresponding fractal dimensions. (From Ref. 18.)

microscope, and expressed in various parameters including fractal dimensions.

The angle of repose of granules prepared by five different methods was found to be primarily a function of surface roughness. The Hausner ratio (discussed later) has been related to the morphological properties of sands (23).

The shapes of components being mixed have a great impact on the mixing rate and the physical stability of the resultant mixture. Lactose and calcium carbonate of different particle shapes were mixed in a Y-cone mixer. The time required to achieve an acceptable standard deviation of mixing σ_A increased with the irregularity of the particles of both components, and the mixtures containing irregularly shaped particles segregated less on subsequent vibration (24).

Some work has shown a direct correlation between shape factor and the flow properties of powders. The flowability of fine powders, as measured by a shear-cell as well as by Carr's method, was found to increase with increasing sphericity, where the sphericity is indicated by a shape index Ψ approaching one, as measured by an image analyzer (25). Huber and co-workers (26) derived an equation in which flow rate was correlated to the volume specific surface as measured by laser diffractometry. Reasonable predictions were made for individual powders as well as binary and ternary mixtures.

Moisture and Static Charge

The affect of humidity can vary drastically from powder to powder. Absorbed moisture in solids can exist either in the unbound state or as part of crystal structure. It exerts its effect directly by changing the surface properties of the particle. It can also affect flow properties indirectly and permanently through the formation of granules, which are held, together by solid bridges generated by hydration and dehydration of a binder. The process of wet granulation can be viewed as an intentional use of moisture (or other organic liquid) in controlling powder flow properties. Moisture significantly influences powder flowability as measured by the tensile strength of powders by forming liquid bridges. The increase in tensile strength has been translated into increase in torque or power consumption in a mixer and has been utilized for the monitoring of wet-granulation processes. At higher moisture content and higher packing densities, liquid bridges may progress from pendular to funicular bonds. The effect of moisture varies, depending on the degree of packing or the porosity of the powder bed. For a porous and cohesive material, flowability is not affected by moisture since the moisture can penetrate to the inside of particles without the formation of liquid bridges. A single lot of

microcrystalline cellulose NF was placed in various humidity conditions and the moisture content determined through loss of drying (27). Flow parameters were determined through the compressibility index determined by tap density and also through the use of a shear cell. It was shown that increased moisture decreased flow and that once the moisture content of the microcrystalline cellulose exceeded 5% its flow was predicted to be poor. Differences in flow rates of microcrystalline cellulose through an orifice were attributed partially to differences in moisture contents that affected cohesiveness (28). Cohesiveness of two grades of microcrystalline cellulose (Avicel PH101 and Emcocel) measured with a sandwich rheometer, peaks at approximately 20–25 wt% moisture content. Avicel was found to be more cohesive than Emcocel at a moisture content less and 30 wt%, whereas at higher moisture content the cohesive behavior was comparable (29).

Very low moisture can hinder flow since you are more likely to develop electrostatic charging. Particles acquire static charge most commonly through grinding, attrition, and collision, a phenomenon generally known as triboelectrification. Surface charge can also be generated by the sudden separation of their closely contacted, dissimilar surfaces, as in the case of sieving, mixing, or the movement of dry particles through a hopper or over a belt. Excipient powders are generally charged negatively in contact with metal or glass surfaces, whereas many are charged positively in contact with plastic surfaces (30). Most pharmaceutical excipients have low resistivity and therefore lose electrostatic charge through earth leakage relatively quickly. Electrostatic charge interactions can be controlled with beneficial results in terms of improved physical stability of normally unstable, segregating systems. Physical stability can be improved with or without permanent electrification (31).

Powder Cohesion and Storage Compaction

The storage condition a powder is placed under will have a great affect on the flow characteristics it exhibits. As stated in recent article by Marinelli (32) "as a solid remains at rest in a bin or hopper, it can become more cohesive and difficult flowing." Hopper and bin load levels, vibratory forces, time in storage, temperature of storage as well as the intrinsic cohesiveness of the material will alter its flow characteristics. Shear cells have been designed to measure the cohesion of materials under load and after preconditioning. The nature of these tests and how they work is described in more detail later on in this chapter.

Effects of Temperature

The cohesion of powder as measured in a Jenike or annular shear cell decreases as the temperature is decreased (33). This is attributed to the reduction in plasticity and in the inability of asperities on the surface of neighboring particles to form welded bonds as the temperature of the sample is lowered (34). Similarly, flow rates of powdered sugars and fatty acids through a circular orifice decrease with increasing temperature (35). An increase in tensile strength of powders is also observed for lactose and griseofulvin with increasing temperature and explained on the same basis (36). Pilpel (37) noted that an important property of a powder determining whether or not it was sensitive to temperature changes when studying flow behavior was its homologous temperature. The homologous temperature for any given material is the investigational temperature as a fraction of the melting point of the material in absolute degrees (Kelvin). Stearic acid that has a melting point of 343 K when tested at 25°C (298 K) would have a homologous temperature of 298/343 K equal to 0.87. In his investigations Pilpel found that powders started to have less flowability at homologous temperatures above 0.9. As you would suspect materials with lower melting points will have more flow problems than would higher melting point solids. Pilpel also noted that when powders that would not flow out of a funnel at room temperature were cooled to -25°C they flowed easily.

MODELS OF HOPPER FLOW

The design of hoppers and bins has been studied extensively in the last 35 years especially in the mining, food and chemical industry. Due to the large volumes of powders handled in these industries the design of storage and handling materials are a major investment. During the late 1950s and early 1960s Jenike employed a soil mechanics approach to powder handling, developing a logical, theoretical basis for bulk solids flow (38). In general, two flow patterns can be used to describe material flow through a hopper, although systems exist in between. When materials flow by gravity, the entire content of the hopper moves together and the material discharges on a first-in first-out basis. This is the case of mass flow. When the movement is restricted to a central region, leaving a relatively stationary zone in the periphery, the situation is known as funnel flow or core flow. Alternatively, flow blockage occurs by doming or bridging where a stable arch is formed across the outlet of a hopper (Fig. 2a). With highly cohesive powders or poorly designed hoppers when the gate is opened only the material above the opening

flows out and then no further flow occurs. This is an extreme funnel flow condition known as rat holing or piping (Fig. 2b). Mechanical and structural arches are stable obstructions formed when particles come together to form a weight bearing arch, much in the same way a stone bridge is formed. This type of arch can be avoided by making sure the opening is of sufficient width to allow the particles to pass through. For cones the rule of thumb is that the opening should be six to eight times the largest particle size (39), 10 times has been mentioned by Jenike (38). The more troublesome arch is a cohesive arch. This type of arch is formed through compaction and cohesion of the material in the hopper. Bates (40) defines cohesive arching as "the formation of a stable flow obstruction over an outlet or within a flow channel due to the bulk strength of the material exceeding the unconfined failure strength at which the span of the arch would collapse because of the stresses acting on the mass." The design of a mass-flow hopper is based on the postulate that gravity flow of a solid in a channel takes place, provided that the yield strength that the solid develops as a result of consolidation is insufficient to support an obstruction to flow. The calculations for hopper dimension are based on an assumption of the stress pattern that may exist in the hopper in the static condition that is expressed as a flow factor (ff), which is the ratio of the maximum principal stress at two difference points, as shown by

$$ff = \frac{\text{Maximum principal stress encountered within the hopper}}{\text{Maximum principal stress at free surface}} \quad (2)$$

Fig. 2 Flow patterns: (a) doming; (b) piping or rat holing in obstructed flow.

The hopper design, therefore, requires the maximum principal stress at the outlet to be greater than the unconfined yield stress of the powder material. The two stresses may be compared graphically by plotting the flow function of the material (FF) and the flow factor of the hopper (ff) on the same fc vs. σ_m plot. The point at which the hopper stress and the material strength are equal is known as the “critical unconfined yield stress;” it must be determined when calculating the size of the hopper outlet. The hopper flow factor is obtained from figures described by Jenike (38) and come from shear cell measurements described later on in this chapter.

If the hopper-flow factor lies above the powder-flow function, cohesive arching is not possible with the material in that hopper. If the hopper factor lies below the powder-flow function, arching of material in the hopper is possible even for large-outlet sizes.

Various shear cells have been developed to aid in obtaining the needed information to determine the functions necessary to design mass flow hoppers, bins and silos. In addition to powder shear, wall friction testing (41, 42) and compressibility (43) as well as other testing all enter into hopper design. This chapter can only briefly touch on the theories and test methods that go into hopper design. Various recent texts (44–46) give a much more in depth treatment of the subject. Various web sites such as www.powderandbulk.com have been the source of updates in this area.

Prescott and Hossfeld (47) have written an article relating hopper design directly to pharmaceuticals, most specifically to the tabletting process. Mechanisms of segregation in the hopper are discussed and case histories of how hopper designs and inserts, which aid flow, can help solve these problems. Since the hoppers for tablet presses as well as capsule filling equipment are specifically designed for this equipment and since in the pharmaceutical industry a variety of materials must be handled by the same equipment, the use of inserts might be a relatively inexpensive fix for flow problems. Bates (48) discusses the use of inserts in hoppers and Troxel (49) also discusses the use of mechanical flow aids such as vibrators, air cannons as well as chemical flow aid, which are discussed in the next section.

FLOW ENHANCERS (GLIDANTS)

To improve the flowability of powders and granulations, a small amount of a flow agent, or glidant, is often added, usually in powder form. Commonly used glidants are colloidal silicone dioxide, talc, and starch. Several

postulates have been proposed for the mechanism of glidant action (50–52).

- Dispersion of static charge from the surface of host particles;
- Distribution of glidant in the host particles;
- Preferential adsorption of gases and vapors otherwise adsorbed onto the host particle;
- Physical separation of particles and subsequent reduction in van der Waals interaction; and
- Adsorption of glidant particles to granulation surfaces in such a way that friction between particles and surface rugosity are minimized.

The effects of a glidant on the flowability of a powder depend on many factors, such as physical and chemical affinity for the powder, the average particle size and shape in relation to those of the powder, concentration of the glidant and degree of mixing, as well as the moisture content. To be effective, in general, the glidant particles should be very much smaller than those of the host powder in order to coat them completely, smoothing out irregularities in their shape, and reducing the frictional and adhesive forces that operate between them. In almost all systems, there is an optimum concentration above which the glidant ceases to be effective. If too much is added, powder flowability may decrease, and it is therefore necessary to control the addition carefully for the best results. Glidants probably have mainly a mechanical action. They adhere to the surfaces of host powders, smoothing out irregularities and reducing their tendency to interlock mechanically during movement and flow. If the particles of the glidants are assumed to be spherical in shape with a radius r and are uniformly closely packed to those of the host, which are also assumed to be spherical with the radius R , optimum flow should occur when the mixture contains approximately $(2\pi r(R+r)^2/100/R^3)\sqrt{3}\%w/w$ of a glidant (53). A 100- μm powder requires about 3% of a 1- μm glidant, which is in reasonable agreement with experimental observations. The type of glidant, the mixing factors, and the nature of the formulation all will have affects on the reliability of this equation.

Colloidal Silcion dioxide is an agent that has been commonly used as a glidant. Flow rate, density, as well as other related measurements, were conducted on four different excipients. The addition of 1% colloidal silicon dioxide increased the flow of the poorer flowing excipients but had lesser affects on the exipients that were of larger size and were better flowing (54). Increasing amounts of chlorpromazine hydrochloride markedly decreased the flow characteristics of all the various blends. The particle size of the excipient blend seemed to grow larger with the addition of the chlorpromazine hydrochloride since it is

believed that the drug stuck to the surface of the excipients. The addition of 1% colloidal silicon dioxide negated the negative affects of the drug. The addition of the colloidal silicon dioxide decreased the particle size increases caused by the addition of drug. It is believed therefore that a possible mechanism of the silicon dioxide was to prevent the drug from coating the excipient particles and reducing flow. Scanning electron microscopy corroborated this conclusion. In another work (55) the amount of silicon dioxide was varied from 0–2%. It was shown that 0.5% addition of the glidant caused a marked reduction to the weight deviation of tablets produced on a single punch tablet press. The standard deviation of tablet weight did not further reduce when greater than 0.5% of colloidal silicon dioxide was added to the formulation showing a limit to its effectiveness. In a recent article (56), 2% colloidal silicon dioxide was shown to be affective in improving the flow of micronized ibuprofen powder in powder layering.

Magnesium stearate, which is better know as a lubricant, has also been shown to have glidant properties. Shear cell studies with eight different materials with varying size and shape showed that the optimum amount of magnesium stearate that affected flow was related directly to particle size (57). In another study mixing time and type of mixer had a marked affect on the flow of lactose containing 1% magnesium stearate (58). These experiments demonstrate that magnesium stearate becomes increasingly affective as a glidant as it coats the material. The surface area needed to be covered and the shear and duration of the mixing are primary variables in determining the optimal glidant concentration of magnesium stearate.

MEASUREMENTS OF FLOW PROPERTIES

Flow Through an Orifice

During the manufacture of tablets, granulations must first flow through a stationary orifice, the outlet of a hopper, followed by flowing into moving orifices, that is, tablet dies. The first type of flow, static flow, has been investigated extensively. Equations developed for modeling static flow, W_s , through an orifice of diameter P , are often based on the Brown–Richards equation and are written as

$$W_s = f(d)P^{b(d)} \quad (3)$$

Generally f and n denote “function of” and $n(d)$ is generally 2.5. Moreover n has also been shown to be a function of the particle diameter d . Conditions for static

flow where the Brown–Richards equation is applicable are the following (59):

- The flow rate decreases as the particle size is increased;
- The orifice size is at least six times greater than the particle size;
- The granulation height is at least two times greater than the orifice diameter; and
- The ratio of the orifice diameter to granulation hopper diameter is less than 0.5.

The dimensions of a flowmeter should therefore be carefully considered prior to its construction. For example, a flat-bottom flowmeter with a diameter of 6.0 cm, and circular orifices with diameters of 1.428, 0.925, and 0.635 cm and a column height exceeding 18 cm were employed as reported by Danish and Parrott (11). For a flowmeter consisting of a hopper with interchangeable attachments, a top-loading balance with output capabilities, and a digital analog converter, a strip-chart recorder was employed in the evaluation of formulations (60). Criteria for acceptance of prototype formulations were developed, including uniform flow of >200 g/min through a 30° cone, and low through a 12.7-mm straight-bore attachment of $7 > 2000$ g/min.

Some formulations can flow too well and upper limits are required based on the capacity of the tablet press under consideration.

A flowmeter is generally capable of measuring the flow rate of powders that flow well. For cohesive materials the minimum orifice diameter necessary to induce free flow was reported to be a better index of flowability (61).

Several studies were conducted to investigate the relationship between the orifice flow rate and the failure properties of powder materials. It was indicated that a simple linear relationship between flow rate and tensile strength would exist only when the powder system is sufficiently cohesive to produce measurable tensile strength of a consolidated powder but sufficiently free-flowing to produce a gravity flow under an unknown and changing consolidation state (62). For less easily flowing powders the hopper may be vibrated to facilitate flow in order to measure flow rates.

A flow device was developed with movable orifices that attempted, through the geometry of the system, to eliminate wall friction as a factor (63). Most consistent results were obtained when a stainless steel cylinder was used as the main hopper. The orifice was a movable end piece with different size holes. In order to select the best excipients for the direct compression of microtablets a funnel flow device, using interchangeable orifices was used. The lengths of the orifices were also varied to keep the angle of inclination constant (64). It was shown that

flow rates could be estimated even for narrow orifices. The Carr index and Hausner ratios, which will be discussed in the next section, of the excipients was also determined and used in the excipient evaluation. In a more recent paper (65) a funnel method was used to evaluate a number of sustained release theophylline microtablet formulations. Colloidal silicon dioxide was added to the nonflowing granulations and then measurements were taken. The angle of repose was also measured for all of these formulations. A number of papers in the last 10 years, in addition to the ones already discussed, use flow rate measurements to evaluate pharmaceutical formulations and excipients (66–73) and almost all combine the hopper flow measurements with other measurements, such as angle or repose and Carr Index. In summary, flowmeters are a practical way of screening powders with good flow and distinguishing good flowing materials from poorer flowing materials. Since all materials don't flow well enough for evaluation, flowmeter measurements are often used in combination with other measurements for formulation flow evaluation.

Empirical Measurements of Powder or Granular Properties

A number of tests such as contact angle, bulk density, and tap density are relatively simple tests that, though not direct measurements of flow, have been found often to be predictive of the flow characteristics of materials. This is because these measurements are highly dependent on particle size and shape and the cohesive nature of the material, all of which are chief variables in the flowability of solids. These tests are commonly used in combination and are still routinely being conducted and related to flow in every-day pharmaceutical development.

Angle of Repose and Other Handling Angles

If a powder is allowed to flow onto a flat surface, a pile or heap of powder is formed. A material that is not cohesive and flows well, spreads out, forming a low heap. More cohesive materials form higher heaps, which are less spread out. The angle of repose is defined as the angle of the free surface of a pile of powder to the horizontal plane. Pharmaceutical powders give two main types of angle of repose: the poured angle, which is the angle measured on a pile poured freely onto a flat surface; and the drained angle, which is the angle measured on the conical surface of powder in a flat-bottomed container, if the powder is discharged through an orifice in the base. The poured angle of repose can be determined by any

device that allows a standard method of pouring the powder onto the flat surface and measuring the angle of the resulting heap. A protractor is commonly used or the base of the heap is controlled and the height of the heap is measured (Fig. 3) (74).

The drained repose angle is obtained with flow devices as described previously. The measurement is affected by the degree of consolidation of the material in the hopper. The drained angle is usually larger than the poured angle for the same powder. Just as the flow rate is affected by the size of the orifice and the particle size of the powder, so is the drained angle. Pilpel (75), recognizing the effect wall friction could have on the drained angle, reported on a device in which the powder is initially placed in a large container with a built-in platform. The powder is allowed to flow out at the bottom, leaving an undisturbed conical heap on the platform, thus eliminating wall friction from the measurement. Carstensen et al. (76) demonstrated that the frictional force between the support base and the granulation plays a significant part in the repose angle of a heap of granules on a plane surface. This means that even the Pilpel device as well as poured-angle measurements would be affected by frictional factors. Jones and Pilpel (77) tested a number of devices and showed that the measurements obtained were highly dependent on the device. In a review article (78), Pilpel states that since the angular properties of powders are so dependent on the details of measurements, they are useful only in a qualitative manner. For this reason, the shear cell has replaced the repose angle measurement as a quantitative method to detect the cohesive characteristics of powder.

Fig. 3 The angle-of-repose plate incorporates a protractor, an indicator wire, and a jarring device for angle-of-fall tests. (From Chem. Engi. 1965, 18, 164.)

In addition to measurements of poured and drained repose angles, several other handling angles have been utilized. By placing the powder on a smooth surface (slide) and finding the minimum slope that causes the powder to slide, the angle of the slide is obtained. It is highly dependent on the material over which it slides (79), and can be useful in designing hoppers or conveyers. Another angle that has been utilized is the angle of spatula, which is measured by lifting powder with a flat spatula and measuring the angle the heap of powder forms with the spatula surface. Carr (74) standardized this method and utilized it with several other parameters to characterize powders. Characterization numbers are discussed later. The angle of spatula serves as a very simple but rough method of characterizing a powder with respect to flow. A vibrating spatula has also been used in recent years and this will also be discussed in a later section (20, 80).

Dahlinder et al. (61) developed a new device to measure the drained angle of repose. It consists of a split cylinder, which contains a flat circular platform. To measure the angle of repose, the cylinder is filled with powder. The cylinder is split, allowing the powder to fall into a heap on the platform. This device is similar to Pilpel's (75) but eliminates wall friction during the flow by utilizing the split cylinder to initiate flow. Dahlinder tested sodium chloride, microcrystalline cellulose, and aspirin powder as well as lactose, lactose-cornstarch, and aluminum hydroxide-magnesium carbonate granules. The resulting angle-of-repose measurements were reproducible (relative standard deviation about 2%). The authors concluded that this method could be used to characterize even fairly cohesive materials. Nyqvist and Nicklasson (81) utilizing Dahlinder's repose-angle device tested direct-compression lactose containing small concentrations of various actives and found a linear relationship of the angle of repose to the coefficient of tablet-weight variation. Nyqvist (82) found that when testing penicillin granulations the Dahlinder repose-angle results did not give any specific ranking order for the pure drug substance or the granulation. In contrast, annular shear cell data were able to predict the flow behavior for tablet production. Most recently Parrott (83) utilized a poured angle measurement to compare Soludex, a corn-based maltodextrin, to nine commercial excipients. He also used flow through a fixed orifice, and found that the flowmeter represented the flow of the materials better than the repose angle. However, several ingredients did not flow at all through the orifice, and the angle of repose represented the only comparative value for the 10 excipients investigated.

Heistand (8) and Carstensen (84) related the repose angle to the intrinsic cohesion and frictional coefficient of

powders. As mentioned previously, the dependence on the technique used makes this method much less reliable for this purpose than a shear cell. In addition, the repose angle does not quantitatively treat the compressive forces of the flow process in the same way as the shear cell. As Pilpel mentioned (79), angular tests are applicable to relatively free-flowing powders containing particles larger than 100 μm . Such powders cannot be investigated in the scientifically more satisfactory shear cell and tensile strength test apparatus because of their low cohesion and tensile strength. Furthermore, the particles become crushed on consolidation. Today angular measurements continue to be used with mixed results, as shown by the previous examples. The test, usually in combination with other tests, provides a simple and sometimes useful method for monitoring the characteristics of powders and granules for quality control purposes.

Packing Properties and Bulk Densities

The bulk density of a powder is obtained by dividing its mass by the bulk volume it occupies. The volume includes the spaces between particles as well as the envelope volumes of the particles themselves. The true density of a material (i.e., the density of the actual solid material) can be obtained with a gas pycnometer. The bulk density of a powder is not a definite number like true density or specific gravity but an indirect measurement of a number of factors, including particle size and size distribution, particle shape, true density, and especially the method of measurement. Although there is no direct linear relationship between the flowability of a powder and its bulk density, the latter is extremely important in determining the capacity of mixers and hoppers and providing an easily obtained valuable characterization of powders.

Aerated bulk density

This is the bulk density of a powder after it has been allowed to aerate, that is, in most cases flow. A number of commercial devices are used to obtain this value. These devices allow the powder to flow from a fixed height, usually through a set of screens, into a container of fixed volume. An excess of powder is used and cleared from the top of the container, the tared container is then weighed. The bulk density is the weight of the powder divided by the volume of the container. The device can be as complex as a series of vibrating screens or as simple as pouring powder through a screen into a tared graduated cylinder. The cylinder is placed on a tapping device to measure the tap or, as Carr (74) defines it, the packed bulk density. Some tap the cylinder three times in order to level the

powder and get a more uniform result. The leveling of the powder can also be critical in other devices. The author utilized a device known as a Scott volumeter in which powder is passed through a series of glass baffles before falling into a tared cubical container. The excess powder is removed, so that the powder is flush with the container top. Considerable operator variability between tests has been noted, and it was found that the pressure in removing the excess powder varied between operators; this was the chief source of variability. A standard wiper method was developed and solved the problem.

Tapped or compressed bulk density

Tap density is the bulk density of a powder which has been compacted by tapping or vibration following a specified procedure. A large number of machines are available to measure tap density; some use a fixed volume of powder and some a fixed weight of powder. The sample is dropped (tapped) a set distance at a set frequency for a fixed number of times. Vibrators of known frequency have also been used for compaction. A simple device, developed by Neumann in 1953 (85) is shown in Fig. 4. It uses a cut cam, which allows the powder to drop exactly 1 cm each revolution. In tap devices the machine can be set to stop after a certain number of taps and the volume is measured. The sample is usually tapped or vibrated until an equilibrium volume is obtained and at that point the final tap density is determined. The rate of tap density can also be measured by recording the density after a given number of taps or vibrating for a given amount of time, and repeating the process until no change in volume occurs.

Density and flow

Carr (74) reported that the more a material is compacted in a compaction or tap bulk density test, the poorer its flow properties. He defines compressibility C by

$$\%C = 100(P - A)/P \quad (4)$$

where P is the final tap or compacted bulk density and A the aerated bulk density. A more commonly used term is the Hausner ratio, which is simply P/A , the final tap density divided by the aerated bulk density. This ratio was introduced by Hausner in 1967 (86) to characterize metal powders, but is commonly used today for pharmaceutical powders. The higher the Hausner ratio, the poorer the flow. Neumann (52) reported that the higher the rate of packing (fewer taps to reach equilibrium), the better the flowability. He also experimented with weights to compact the powder. He plotted the log of the relative volume obtained with a given weight vs. the log of the weight used; linear plots are produced. Chowhan and Chow (87)

Fig. 4 Tapping device. (From Ref. 85.)

used a modified version of Neumann's device in which they placed loosely packed powders and powder mixtures in cylindrical containers and applied a series of loads to the surface of the powder beds. They tested a drug with various excipients and plotted the log of the relative volume vs. the log of the relative weight utilized. They also obtained linear plots and called the intercept on the relative volume axis the powder-consolidating ratio. This value yielded a linear correlation with weight variation for capsules filled on a Zanasi capsule-filling machine.

Varthalis and Pilpel (88) derived a relationship between tensile strength and packing rate with lactose and paracetamol and, alternatively, lactose and oxytetracycline. From this relationship they developed a measure of powder flow and packing in terms of the "angle of internal flow," an empirically derived parameter, for the rate of change of bulk density with tamping. Newton and Bader (13) utilized this parameter and related it to the fill weight of capsules containing aspirin and lactose. Attempts to relate it to in vitro release of the aspirin were not successful. In the first of a series of articles regarding lactose coated with nonionic surfactant, Sakr and Pilpel (89) utilized tap density to explain the surface effects of the coating. Yamashiro et al. (90) used very short

tap intervals (stopped and measured after one or two taps) to test an equation stating that the number of taps divided by the relative volume of the powder after these taps is linearly related to the number of taps. When this relationship holds, the flow rate of a material can be related to the proportionality constants.

In conclusion, tap-density methods are a quick and inexpensive way to characterize materials. A strictly empirical relationship exists between the degree of compaction and powder flow. If viewed in this light, tap density can be a useful measurement technique.

CLASSIFICATION SYSTEMS

In 1965 Carr (74) proposed a characterization system that has been used extensively to classify pharmaceutical powders and granulations. The method consists of a point system that weighs four factors equally, giving each a maximum of 25 points with a maximum of 100 for a perfectly flowing material. The first measurement is the angle of repose. A diagram of the apparatus used by Carr and a discussion of angle of repose appear earlier (Fig. 3). According to Carr, the contact angle is a simple and easy method of indirectly measuring the following properties affecting flow: shape, size, porosity, cohesion, fluidity, surface area, and bulk density. The second factor, also discussed previously, is compressibility as obtained from tap density. Carr defined compressibility by Eq. 4 and claimed that the percent compressibility indirectly provides an excellent representation of uniformity in size and shape, deformability, surface area, cohesion, and moisture content.

The third factor in Carr's characterization scheme is the angle of spatula. As mentioned previously, Carr designed a special method for measuring this angle. According to him, the angle of spatula is an indirect measure of cohesion, surface area, size, shape, uniformity, fluidity, porosity, and deformability.

The last factor is either the cohesion or the coefficient of uniformity. Cohesion is used with powders (very fine particles) or with materials on which an effective cohesion force can be measured. The uniformity coefficient is used with granular and powdered granular materials on which an effective surface cohesion cannot be measured.

The procedure for finding the apparent surface cohesion involves determining the retention of material on a nest of 250-, 150-, and 74- μm (60-, 100-, and 200-mesh) screens over a bottom pan. A weight of 2 g of test powder is recommended to be placed on the 250- μm (60-mesh) screen, followed by vibrating the nest of screens for

20–120 s. The amount of material left on each screen is weighed and rated in points or percentage. Accordingly: each 0.1 g on the 250- μm (60-mesh) screen corresponds to five points or 5%; each 0.1 g on the 150- μm (100-mesh) screen corresponds to three points; and each 0.1 g on the 74- μm (200-mesh) screen corresponds to one point. If the entire amount of material passes through the 74- μm (200-mesh) screen, the cohesion is zero. Electrostatic attraction of some particles and the tendency of smaller particles to adhere to larger particles can skew the result. The particle must be 74- μm (200-mesh) material in order for the test to be attempted.

The uniformity coefficient is arrived at by dividing the width of the sieve opening that passes 10% of the sample. It is determined from a screen analysis of the material. The more uniform a mass of particles is in both size and shape, the more flowable it is likely to be.

The point score for the evaluation of flowability of dry solids is given in Table 1. In order to measure the flowability of a powder utilizing this method, each test is made and the points can be found in the table. The total number of points would place the sample into one of the seven categories in the left column of the table. Because of its simplicity and the fact that commercial devices are available to conduct these tests (this test is ASTM test designation D 6393-99), this system is widely used in the pharmaceutical industry both in preformulations, formulation research, and in quality control.

Other classification systems are used less frequently. Carr (74) also devised a system to classify materials as to their floodability. He defines the floodability of a material as its tendency to flow like a liquid because of the natural fluidization of a mass of particles by air. In order to so classify a material, the flowability is determined utilizing the method just described. This value is equivalent to a measurement Carr calls the angle of fall, angle of difference, and dispersibility. Though referred to in any of the papers mentioned here, this system is much less utilized than the flowability measurements. Geldart (91) reported on a characterization system of powders according to their ability to aerate and later Molerus (92) modified this system. In a more recent symposium this method of powder classification was examined (93–95).

As mentioned in previous sections of this article, the Carr index as well as other empirical tests such as the Hausner ratio continue to be used, often in combination with other tests to characterize and predict the flow of pharmaceutical excipients and formulations. In addition to papers already discussed in this article a number of papers have appeared in the more recent pharmaceutical literature in which these methods have been used to classify the flow characteristics of pharmaceutical

Table 1 Point scores for evaluation of flowability of dry solids

^a Used with granular and powdered granular materials.^b Used with powders or where an effective cohesion can be measured.(From Chem. Eng. **1965**, 18.)

powders (93–101). Sugar based excipients (96), granulated lactitol (101), microcrystalline cellulose codried with β -cyclodextrins (100) and various phyllosilicate powders such as bentonites (97) were characterized through Carr index measurements. With the phyllosilicate powders the authors noted that hopper flow values were of little use due to very high standard deviations and the angle of repose measurements and Carr index and Hausner Ratio were considered more relevant to their characterization. In the microwave drying of high shear granulations, the Carr index decreased with increasing microwave power due possibly to an increase in dust formation (98). Hausner ratio and slowing of the rate of taping was used to show that moisture increased the interparticular friction of Avicel PH 302 (99). Angle of repose along with flow through multi size orifices were used to characterize the flow of several dextrins (93). Another example of the use of Carr's indexing method is given in a paper by Vennat

et al. (102) where the flowability and floodability index of a group of direct-compression excipients and procyanidins are reported. The material was tested in the commercial Hosokawa powder characteristic tester. Only angle of repose and taped and bulk densities were used to classify the rheology of Avicel PH-200 and Cellactose (94, 95).

In summary, Carr's flow characterization method is frequently used for characterizing powders. No one method alone gives a total picture of flow and hence a combination of methods is often used. If known forces are being utilized during the flow process, a shear cell would be the method of choice when a scientifically based characterization is needed. If granulations are being tested with good flow characteristics, a flowmeter might be the method of choice. A combination of empirical tests, for example, Carr's flowability test, would be very useful as a simple screening device or as a quality control test for multiple lots. The selection of the method should be based

on the amount of information needed and the material to be tested, and may be more importantly, the equipment available.

SHEAR CELLS

The flow through an orifice is an excellent method to compare materials with good flow. Pharmacy, however, most often deals with cohesive powders that do not readily flow. The flow of these materials is increased by employing force feeders, resulting in a dynamic process. Angle-of-repose measurements that do not utilize force and that are often a measurement of stagnant powder have therefore limited application. Shear testers, that measure the frictional characteristics of a powder bed under load, yield valuable information with regard to powder flow in high-speed tablet- and capsule-filling equipment.

Data Treatment

A number of different types of shear cells are discussed in this section. Each of these cells is designed to condition the powder under a known force, and measure the force needed to shear the powder bed under a load force equal to or less than the original conditioning force. For each conditioning force, the force needed to shear the bed for a series of loads is plotted against the load force in a similar manner in which a frictional coefficient is determined for a nonpowdered material. Such a plot is known as a yield locus (Fig. 5), and it is often obtained for a number of different conditioning forces. Thus, if the forces acting on a material in a given process can be approximated, intrinsic information regarding the frictional and cohesive nature of the material can be obtained that should have great relevance to real processes.

Fig. 5 Mohr circle construction to obtain the major normal stress, σ_m , and the unconfined field stress, f_c . (From Ref. 78.)

The most common method of treating shear data is the Mohr circle analysis, also shown in Fig. 5. The x -axis represents the stress normal to the shearing power (load stress), and the y -axis represents the shear stress. The curve represents the yield locus for a cohesive solid. The intersections of the Mohr circles are drawn in such a way that they are tangent to the yield locus. These circles represent the total forces on the powder bed at the point of shear for any direction. The point at which the Mohr-circle-drawn tangent to the upper end of the yield locus (2nd Mohr circle) intersects the x -axis at the highest point is known as the principal normal stress σ_m . This value represents the maximum normal stress under which the powder was consolidated before it yielded and changed volume. Drawing a Mohr circle that is tangent to the yield locus and passes through the origin gives a value known as the unconfined yield locus f_c (the point where the Mohr circle intersects with x -axis). This value represents the maximum principal stress acting on a free surface necessary to cause failure. Jenike (38) related this value to the strength of an arch in a hopper. For a cohesive solid, the intersection of the yield locus with the y -axis (shear stress) is considered the cohesion of the powder for that yield locus. The point at which the yield locus intersects the negative x -axis is considered the tensile strength of the material compressed under the normal load used to generate the locus. Most often a series of conditioning forces is used, giving a series or "family" of yield loci (Fig. 6a). A plot of the unconfined yield locus f_c vs. the principal consolidating force for a series of yield loci has been used by Jenike (38) as a flow (or failure) function. Each of these values has been used to classify material as to their flowability.

Eq. 5 describes the yield locus. As early as 1965, Eq. 5 was established empirically from a study of the shapes of yield loci for more than 30 powders (103):

$$\ln[\tau/C] = (1/\eta) \ln[(\sigma + T)/T] \quad (5)$$

where τ is the shear stress, σ the normal stress, T the tensile strength, C the cohesion, and η the shear index. It is often referred to as the Warren–Springs equation and has been confirmed by numerous authors (104–106). Earlier in this article it was mentioned that Geoffroy and Carstensen (14) modified this equation taking particle size of the material into affect. Hiestand (106) states that the Warren–Springs equation is suitable for describing the yield locus for failure in shear. However, contrary to common usage, the term T is not the tensile strength but the internal cohesion, the magnitude of which may be much less than the tensile strength. As stated by Hiestand, this is contrary to the common usage of the equation. He based his conclusion primarily on experimental data with sitosterols. In contrast,

Fig. 6 Families of yield loci for lactose powder coated with $0.5 \times 10^{-5} \text{ mol g}^{-1}$ of light paraffin at 20°C . $P_f \blacktriangle$, 0.346; \times , 0.282; \bullet , 0.279; \circ , 0.261; (a) normal stress; (b) compound stress. (From Ref. 107.)

Irono and Pilpel (107) modified the treatment of the shear data (Fig. 6b). In this figure they added tensile strength values obtained independently in the tensile-strength measuring to the normal load in the shear cell loci plots.

The actual method used to treat the data varies with respect to the nature of the shear cell utilized. Direct measurements of the various functions such as tensile strength and unconfined yield strength have been taken. The following section describes the methods being utilized and their advantages and disadvantages and how they have been applied to the flow of pharmaceutical powders. A detailed description of data evaluation is not included. Several excellent reviews of shear and tensile measurement are available and can be found in the references. Johanson, who teamed with Jenike in conducting much important work in the field, has published an interesting historical perspective of the field (108).

Fig. 7 The Jenike shear cell. (From York, P. *Int. J. Pharm.* 1980, 6, 101.)

Jenike Shear Cell

This instrument was developed first for soil testing and adapted by Jenike to measure cohesive powders and relate the data to hopper flow and hence hopper design. This is essentially the standard cell (Fig. 7) and the basis of much of the data solids-handling work. It is split horizontally; the lower half is fixed and the upper half is moveable at a constant low rate. The cells are first filled with sample and then consolidated by placing a load on the loading lid (Fig. 7a) and rotating the lid backward and forward through a slight angle. The loading lid and molding ring are removed and the powder scrapped level with the top of the upper half of the cell. The shearing lid is placed in position and the cell is sheared by moving the upper half over the lower fixed portion. The load is equal to or lower than the consolidated load. The process is repeated with the same consolidating load but with lower shearing loads until the yield locus is obtained. If a family series of yield loci are to be developed, a series of consolidating forces are used. A flow-factor plot should be based on at least three consolidation pressures. Needless to say, this process is extremely time-consuming and tedious. Another disadvantage is that correct consolidation of the sample is difficult to achieve. For this reason the results may be very operator-dependent. Correct consolidation is generally established by preliminary experiments, which examine the shape of the stress-strain curve obtained during shearing. Despite these difficulties, the Jenike shear cell has been used extensively and is commercially available. A number of papers have appeared in the pharmaceutical literature describing utilization of this device (103–116). Doelker (109) in comparing various microcrystalline cellulose types states that techniques such as the Hausner ratio and Carr index are poorly reproducible and can be compared only if determined by

Fig. 8 The plate-type shear cell. Key: (A) lower plate; (B) template; (C) upper plate; (D) tow line; (E) cantilever strain gauge; (F) screw jack. (From York, P. *Int. J. Pharm.* **1980**, *6*, 100.)

the same authors. He states "A more trustworthy method for evaluating the flow characteristics of cohesive powders is to use shear cells." He goes on to review various flow measurements of microcrystalline cellulose as well as other commonly used direct compression excipients.

Plate-Type Shear Cell

Nash et al. (117) and later Hiestand et al. (118,119) developed a very simple test device that can be easily constructed (Fig. 8) and was used to evaluate pharmaceutical powders. The powder is placed between two plates, usually with the surface in contact with the powder consisting of sandpaper or other rough surface to ensure that the powder shears in the bed rather than at the surface of the plate. A consolidating weight is placed on the upper plate. Final consolidation is achieved by shearing, using very short movements in such a way that a reading from the strain gauge is obtained. This is repeated until the shear force, read on a chart recorder, reaches a plateau value. A lower weight is then placed on the upper plate and a lower point in the yield locus is obtained through a single shear movement. The entire process must be repeated for each point in the yield locus.

As with the Jenike cell, this process is time-consuming. Amidon and Houghton (111), however, used a single yield locus with this cell for comparative purposes. Hiestand et al. (120), in comparing this apparatus to the Jenike cell, claimed that this simple shear cell can be used to provide characterization of the unconfined yield strengths of powders. The results from the two devices are not identical. However, as much as the Hiestand device requires less powder and the consolidation step is more automated and consistent, it provides an inexpensive alternative to the Jenike-type cell to characterize pharmaceutical powders. Amidon and Houghton used the cell to examine the effect of moisture

on the powder flow properties of microcrystalline cellulose (27).

Ring or Annular Shear Cell

The ring or annular shear cell, was developed by Carr and Walker (121) as early as 1968. In recent years this tester has undergone a number of modifications. Peschl (122, 123) has developed an annular shear cell in which the sample and shear cell consists of a full circle. This contrasts to the earlier cells that have a band of sample on the outer portion of the circle. This was done to eliminate wall friction. It is also rotated very slowly, since at low speed, velocity variability becomes more negligible in the shear measurement. In this way a full ring can be utilized and speed differences in the outside and inside of the ring become negligible. Schulze (124–126) made the latest modifications to the ring cell tester (Schulze tester RST – 01.01). In the Schulze ring shear tester the sample is placed in an outer circular channel. An angular lid, which is attached to a crossbeam, lies on top of the sample. Small bars are attached to the bottom side of the lid and the bottom of the cell to prevent the powder from sliding against the lid or the bottom. The shear cell is rotated while the lid is prevented from rotating by cross beams attached to fixed beam. The movement of the cell with respect to the fixed lid causes the powder bed to shear and load cells attached to tie rods measure the force needed to initiate this. To exert weight on the sample, weights are hung from a crossbeam. This can be done during the shearing and conditioning of the powder sample. The cell can also be removed and time consolidation can be conducted by placing weights on the sample out side of the test device, in a similar mannner to that with the Jenike cell. An automatic version of this tester (126) has been developed in which the computer can automatically add loading to the sample and condition it. The instrument can be operated in a manual, semiautomatic or totally computer run mode. Both the earlier annular shear cells, the Peschl or Schulze's RST –01.01 cell have several important advantages over the Jenike-type cell. They offer a constant area of shear. Handling is easier and consolidation and shear are quicker, since after the bed is consolidated, a full locus can be generated without reconsolidating after each load. The consolidation process becomes more automated and uniform, eliminating much of the operator variability in the measurement process. Peschl reported a relationship between tablet weight variation and internal friction as measured by his device (122, 123). The Peschl shear tester has been utilized for shear testing and quality control of pharmaceuticals by at least one U.S. pharmaceutical company as well as in Europe. Nyqvist (82, 127) and

Nyqvist and Nicklasson (81) utilized an annual shear cell with direct-compression lactose and various actives as well as high-dose penicillin products and found that the device was an excellent predictor of flow on a tablet press as related to tablet weight variation. From the shear-cell data it was actually possible to predict the frequency of tablet machine adjustment on a rotary tablet press in the production of penicillin products (82). In 1985 Baichwal and Augsburg (128) employed an annual shear cell to quantify the amount of friction between pharmaceutical powders with various lubricants and a smooth metal surface. More recently Podczek and Miah (57) used a commercial version of a Carr annular shear cell to measure the flow factors for unlubricated and lubricated powders. Schulze (125, 126) demonstrated the ability to differentiate the flow function of lactose with and without the presence of 1% active drug. This same laboratory has also produced a ring shear tester to measure wall friction of bulk solids (129). Schulze (130) provides an excellent review of all the previously mentioned shear devices as well as contact angle, and paddle type testers, to be discussed later in this chapter. He also lists several devices not included in this discussion.

Bi- and Triaxial Shear Cells and Other Related Tests

There are several shear tests as well other related tests, which have been used in bulk solids handling and in the design of hoppers and silos but have not been used extensively to study pharmaceuticals. The monoaxial shear tester, Johanson Hang-up Indicizer and compressibility test are examples of test devices that have been used in the bulk handling industries and are described in Schulze's chapter (130). Enstad and Feise (131) further discuss the uniaxial shear tester which tests powder compacted in one direction. The major discussion in their chapter (131) is a discussion of biaxial shear testers. Though not mentioned in the pharmaceutical literature, this test has received a good deal of attention in the recent powder technology literature with the development of a number of new test devices in the 1990s. There are essentially three types of biaxial testers, those being rigid boundary, flexible boundary, and mixed boundary testers. The rigid boundary tester is the one used most for the measurement of mechanical behavior of particulate solids. The sample is brick shaped and the set-up insures that the sample will always retain a rectangular cross-section. In the flexible tester the walls are flexible and made of rubber. Pressure can be exerted via air pressure by inflating chambers within the flexible walls. The mixed boundary

system has only been used at very high pressure with primarily sand. Shearing at constant volume, testing time of loading and varying the direction of loading, and measuring the affects on the stress and strain relationships in the bed are the chief function of this test method. Most of the work with this tester has been with limestone and sand and the results have been used in the design of hoppers. The triaxial shear tester, which was introduced into soil mechanics in the 1920s, has not been used to characterize pharmaceutical powders to any great extent but has been discussed in the powder-handling literature. Luong (132) provides a review of this test method. Kolymbas and Wu (133) gives an extensive discussion of the experimental techniques and the potential errors occurring with the device and how to adjust for them. In a triaxial tester the sample is subjected to pressure in three directions, a pressure chamber usually keeps two of which constant. The cells discussed previously were biaxial with pressure by the normal load and in the direction of shear. In the triaxial shear cell, the sample is placed in a cylindrical rubber membrane and enclosed by rigid end cups. The sample is consolidated by maintaining the same pressure in all three directions, which does not induce shear but volumetric strain. Pressure is usually exerted at the end cups with some sort of a piston that moves in one direction while the pressure chamber maintains the pressure in the other directions. The pressure changes and the volume changes are monitored in all directions. A Mohr-circle treatment of the data is usually made. Certain factors, which are used to evaluate materials, are more directly obtained with this device than with biaxial test devices. The triaxial shear device is still primarily a research tool, and many variations have been constructed. It is less appropriate for flow measurement of pharmaceuticals since it is designed for relatively high pressures.

Johanson (134) developed a very simple device they called the Johanson Indicizer system, or the Johanson Hang-up Indicizer, which they claim can predict material bridging in a hopper. This device was reviewed by Bell et al. (135). In private conversations Johanson stated that they have employed this device with a number of pharmaceuticals. It simply compacts very small amounts of powder into a potential bridge and measures the force to break the bridge and allow the powder to flow. It is not designed to give any detailed information on the powder but only provides a test for powder bridging. This device is commercially available.

Tensile strength can be obtained from shear measurements via the Warren-Springs equation or through extension of the yield locus. The direct measurement of the tensile strength of powders with the help of commercial split-cell devices is common. The powder

is consolidated to a known density, usually through weights. One half of the cell is stationary and the other half is movable on a low-friction surface. The force needed to separate the powder bed at a given density is recorded. In general, a straight-line log-log relationship exists between the tensile strength and the packing fraction (density of sample divided by the true density). Hiestand et al. (106) stated that no method, using loosely packed powder beds, as just described, is highly successful. For this reason, he measured the tensile strength of compacts. Despite his opinion, the measurement of the tensile strength of powder beds continues to be utilized by pharmaceutical scientists. Chowhan and Yang (136) found a linear relationship between tensile strength and the coefficient of variation of the fill weight of capsules. In a separate paper (62) they reported that the flow rate of powder mixtures containing simple glidants, such as corn starch and microcrystalline cellulose, at different concentrations is linearly related to tensile strength. Ho et al. (110) on the other hand, found no relationship between tensile strength and tablet weight variation for a number of direct-compression excipients.

In general tensile strength is not used alone to predict flow. Danjo et al. (25) utilized tensile strength measurement, shear cell measurement, and Carr's flow factor to investigate the effect of particle shape on powder flow.

In summary, various shear and tensile strength measuring devices have been developed, and many are commercially available. Though they are more complex and often more difficult to use than the other methods, they yield data on a more scientific basis, which allows a mechanistic approach to flow problems.

AVALANCHE BEHAVIOR AND POWDER RHEOMETERS

Earlier in this article, in the section on the Affect of Particle Shape, the principle of fractal geometry was introduced. As discussed previously Hickey and Concessio (20) utilized fractal analysis to characterize flow of pharmaceutical powders, using a vibratory spatula. Crowder and Hickey developed a vibratory spatula device that was able to obtain flow data much more rapidly (137). Using this device and fractal geometry, they were able to quantify the differences in the flow properties of sprayed and nonspray dried lactose (80). Kaye et al. also used the vibratory flow of solids to measure avalanches down a shoot (18, 19). Eventually Kaye et al. would use a rotating drum method (138) to study solid flow through avalanching behavior. This device is commercially

available (10) as the Aero-Flow™ automated powder flowability analyzer and is being used in the pharmaceutical industry today.

The theoretical basis for this device can be found in fractal dimensions and deterministic chaos theory. Kaye (139) uses a term known as "fractal dimensions in space" in which he treats fractal data not as a physical structure but as a pattern of events that can be used to describe chaotic systems. He describes deterministic chaos, in the same text, as an interaction of events, which are described by deterministic physics. The interaction of the events become so complex that the system may as well be chaotic. For this reason he has combined fractal analysis with chaos theory to develop an understanding of dynamic particle flow. Hickey and Concessio (140) used this same

Fig. 9 Descriptive drawing of a rotating drum avalanche test device. This device is commercially available as the TSI Aero-Flow automated powder flowability analyzer. The top pictures show the device. The progress of powder avalanche shows the position of the powder in the drum as the drum is rotated and the lower voltage output shows the output of the device during each drum rotation. (From Ref. 10.)

approach in characterizing lactose, using a rotating drum device. In their device they utilized a video camera to measure the dynamic angle of repose with time. The commercial device developed by Kaye works, using light transmission and a series of photocells to measure the light transmission. The device can be seen in Fig. 9.

As can be seen in Fig. 9 the powder is placed in the drum and the drum is allowed to rotate. The powder lifts up and when the dynamic angle of repose is exceeded, the powder sample will avalanche downward. The movement of the powder blocks the photocells from obtaining light and a voltage output, which can be related to the avalanching of the powder is recorded (Fig. 9). A set of data for lactose can be seen in Fig. 10(141).

The flowability of materials according to the literature is related to the mean time for avalanching to occur. The shorter the time the more free flowing. The scatter is related to cohesiveness (10) or an irregularity factor (143). Lower scatter values would indicate a less cohesive material and would predict more regular flow while greater scatter would be indicative of a more cohesive material and the increased likelihood of irregular flow patterns. The example in Fig. 10 shows a lactose sample that was sieved into two fractions: one above 38 μm and one below 38 μm . The middle data is from unfractionated lactose. As can be seen from Fig. 10 that as expected the finer material

had a larger mean and larger scatter showing it to be a poorer flowing material. The larger fraction showed the shortest mean time to avalanche and the smallest scatter showing that it would be the better flowing material. As expected the unfractionated lactose yielded data in between the two fractions. The flow properties of various lots of lactose monohydrate and paracetamol were studied using the Aero-Flo device and lot to lot variations were noted (142). Trobridge et al. (143) tested five grades of lactose with a variable commercial automated drum tester and found that the mean time to avalanche correlated well with flow performance on a tablet press when the drum speed was 180 s/rotation (spr). When the speed of rotation was set at 200 spr slippage was observed with one of the lactose grades and a different rank order was obtained. It was concluded that the fixed speed unit data identified the two optimal formulations but did not distinguish between marginal flow and no flow, but the variable speed unit did. Crowder and Hickey (144) reviewed the physics of powder flow as related to pharmaceutical solids. Included in the article is a section, which explains many of the terminology of complex systems. They include a discussion of avalanching measurement and the use of chaos theory in measuring flow including rotating drum devices. Included in the discussion is powder and granular mixing as well as milling, neither of which is covered in

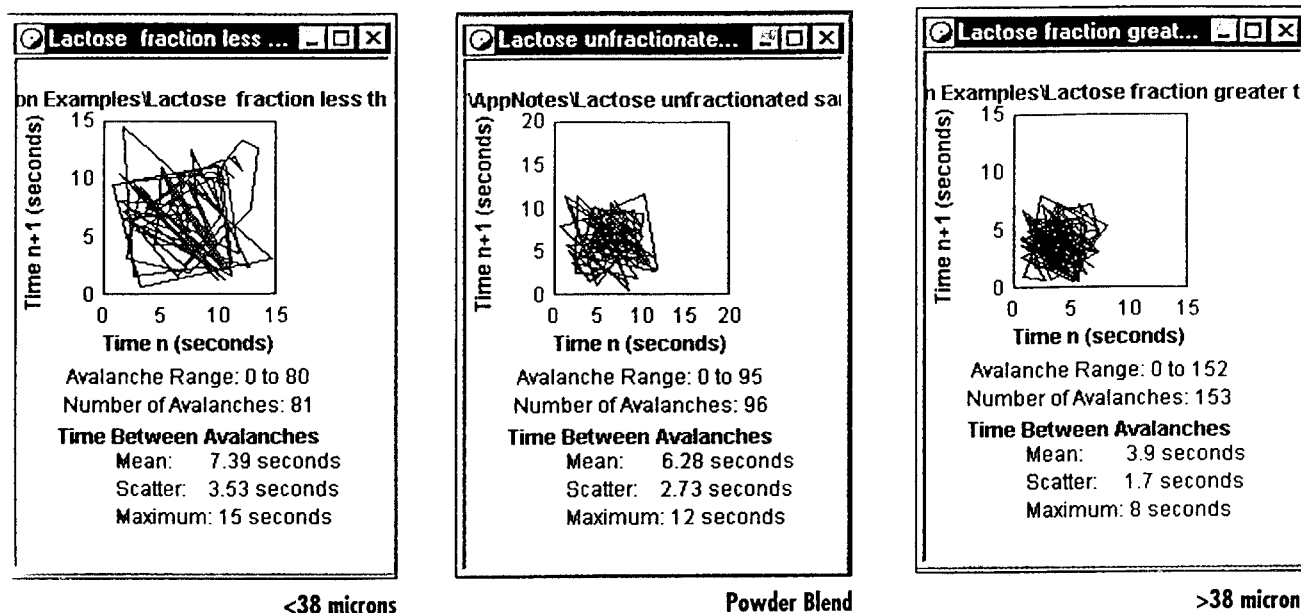

Fig. 10 Rotating drum avalanche data from a TSI Aero-Flow automated powder flowability analyzer. The first frame shows the data output for lactose, which passed through a 38- μm screen (less than 38- μm). The output data for the original lactose sample (not screened) is shown in the middle frame. The last frame shows the flow data for the lactose sample remaining on the 38- μm screen (greater than 38- μm). (From Ref. 10.)

this article, but is also effected by or affect the flow characteristics of solids.

Paddle or blade rheometers are commonly used in to measure the shear of liquids. Brabender (145) developed such a system for solids in which a plate compacts the solid and the torque to initiate turning is measured. Podczek (146, 147) has tested seven different suppliers' microcrystalline cellulose with a new commercial blade type rheometer. In their experiments they were able to measure very small differences between these lots, which they related to actual capsule filling and tablet experiences. The measuring device is commercially available and is now marketed as the FT3 Powder Rheometer (148). (Podczek articles list the instrument as Wet and Dry Powder Rheometer Fingerprint, ManUmit Products Ltd., Bourne End, U.K.) In this instrument the powder is placed in a circular vessel with a closed bottom. The blade enters the powder and moves downward or upward in a helical motion while the force on the blade shaft is recorded. The helical path along which the blade moves is dependent on the axial and rotational speeds and the direction the blade rotates. The angle of approach the blade makes with the powder can be varied, and the direction and angle of the measurement will allow the measurement of compaction, shear and slicing of the powder bed (terms and conditions defined in Podczek's papers). The torque data is treated so as to give theoretically the largest torque exerted by the whole powder column on the rotor blade for a defined test condition. In this way powder shear can be measured under a variety of shear conditions, including various downward compaction modes and upward expansion modes. Podczek (146, 147) found that a downward compaction mode was most sensitive to small differences in the behavior of the various microcrystalline cellulose samples. These differences were not apparent using the Carr compressibility index. Other conditions such as slicing the bed was much less discriminatory. Freeman (149) reported on testing this device with talcum, zinc oxide, and an un-named pharmaceutical. By testing a material and finding the proper test conditions, this device could provide a simple and highly sensitive control test since it is relatively operator independent and yields quantitative values.

CONCLUSION

The final question that should be answered regarding these test methods is which one or ones should you use. Velasco et al. (150) compared data from static angle of repose, dynamic angle of repose, Carr compressibility

index, flow meter, and ring shear test for Ludipress® and Maltrin® M 150 and found a good correlation between all the methods. Tan and Newton (151) compared Carr compressibility, Hausner ratio, angle of repose, and the Jenike flow factor and demonstrated good correlation between all the test methods for five pharmaceutical excipients. They found no correlation between the angle of internal flow and the angle of effective friction. As mentioned previously, differences were seen from slow avalanche results, and faster avalanche results, and other physical measurements (143). As discussed above, rheometer measurements at different conditions (146, 147) and physical measurements for the same powders didn't always correlate.

Two very recent papers compare a number of flow measurement techniques and use statistics for comparison and to devise a new flow index. Lee et. al. (152) compared results from avalanche testing, Carr's compressibility index and critical orifice diameter for six pharmaceutical excipients. Statistical analysis established that there are relationships and similarities between the ranking of powder flow properties between these three methods. They also used a dual approach, which combines visual observation of the type of motion of the powder bed in rotation with the numerical descriptors such as mean time to avalanche and scatter. They found this dual approach was found to be more accurate in the assessment of powder flow than using the numerical descriptors alone. Taylor et al. (153) tested 41 pharmaceutical blends including pure excipients and active blends, using a vibrating spatula, avalanching, critical orifice, angle of repose, and compressibility index. An empirical composite index was established and powder flow was ranked in accordance with formulator experience. Principal components analyses of the angle of repose, percent compressibility, and critical orifice of the powders were also performed. Using principal components analysis, the results of these three tests were statistically weighted to provide a weighted composite index that the authors showed to be the best predictor of flow for these pharmaceuticals. The vibrating spatula and avalanche data were not consistent with formulator experience and cited vendor references for flow. The authors stated that the results of these two test methods might have more relevance if they had used further data treatment such as fractal analysis.

The process of solid flow is extremely complex and dependent on many material and process variables. The answer to the question of which is the best method to use is therefore dependent on your process and what you are trying to predict or measure and select the method or combination of methods that best meets your needs.

FLAVORS AND FLAVOR MODIFIERS

John M. Lipari

Thomas L. Reiland

Abbott Laboratories, Abbott Park, Illinois, U.S.A.

INTRODUCTION

The use of flavors and flavor modifiers to improve the taste and aroma of foods and pharmaceuticals is an art that dates back several centuries. In large measure, the practice is still the same today and, except for the advent of new semisynthetic flavoring agents with improved stability, the field has remained relatively unchanged. In the analytical arena, the story is different. Sophisticated instrumentation methods have been developed to characterize, purify, and manufacture flavoring agents that are similar, in many respects, to those occurring in nature. The technology continues to evolve at an accelerated pace, resulting in several stable, potent, and unique flavors, which are now available to target both foods and pharmaceuticals. This article discusses flavors and flavoring agents typically used in industry and highlights formulation variables that could affect the performance of flavors in finished products. Where necessary, pertinent literature for further reading is cited.

DEFINITION OF FLAVOR

Flavor is the complex effect of three components: taste, odor, and feeling factors. It is usually associated with the pleasure of savoring food or beverages and has, subsequently, suffered from considerable imprecision in definition. Flavor is a sensation with multidimensional components involving subjective and objective perceptions. The sensory perceptions are both qualitative as well as quantitative and, therefore, can be measured. *Webster's New Collegiate Dictionary* defines flavor as the "... quality of something that affects the sense of taste, ... the blend of taste and smell sensations evoked by a substance in the mouth." This definition is correct, but incomplete, and should be redefined to include feeling factors.

Taste

Taste consists of four primary sensations: sweet, sour, bitter, and salty. Correspondingly, there are four different

kinds of taste buds. These sensations are elicited by the tongue and interpreted by the brain. Certain areas of the tongue respond more readily to specific tastes (1) than others. Sweet sensations are most easily detected at the tip of the tongue, whereas bitter ones are most readily detected at the back of the tongue. Sour sensations occur at the sides of the tongue, but salty sensations are usually detected at both the tip and at the sides of the tongue. During ingestion, taste buds react to soluble substances. The resulting sensations are transmitted to the brain by the ninth cranial (glossopharyngeal) nerve. The tenth and twelfth cranial nerves participate in this sensory reaction, but their role is limited (2).

Odor

The odor component of flavor is due to conscious or subconscious reactions to volatile substances, without which most foods would be lacking in taste appeal. By closing the nostrils while eating a mouthful of some flavored substance and immediately following this with another mouthful with the nostrils open, it may be shown that food could be rendered tasteless, as is often experienced by people suffering from the effects of a head cold.
